Über dieses Buch

Dies ist ein digitales Exemplar eines Buches, das seit Generationen in den Regalen der Bibliotheken aufbewahrt wurde, bevor es von Google im Rahmen eines Projekts, mit dem die Bücher dieser Welt online verfügbar gemacht werden sollen, sorgfältig gescannt wurde.

Das Buch hat das Urheberrecht überdauert und kann nun öffentlich zugänglich gemacht werden. Ein öffentlich zugängliches Buch ist ein Buch, das niemals Urheberrechten unterlag oder bei dem die Schutzfrist des Urheberrechts abgelaufen ist. Ob ein Buch öffentlich zugänglich ist, kann von Land zu Land unterschiedlich sein. Öffentlich zugängliche Bücher sind unser Tor zur Vergangenheit und stellen ein geschichtliches, kulturelles und wissenschaftliches Vermögen dar, das häufig nur schwierig zu entdecken ist.

Gebrauchsspuren, Anmerkungen und andere Randbemerkungen, die im Originalband enthalten sind, finden sich auch in dieser Datei – eine Erinnerung an die lange Reise, die das Buch vom Verleger zu einer Bibliothek und weiter zu Ihnen hinter sich gebracht hat.

Nutzungsrichtlinien

Google ist stolz, mit Bibliotheken in partnerschaftlicher Zusammenarbeit öffentlich zugängliches Material zu digitalisieren und einer breiten Masse zugänglich zu machen. Öffentlich zugängliche Bücher gehören der Öffentlichkeit, und wir sind nur ihre Hüter. Nichtsdestotrotz ist diese Arbeit kostspielig. Um diese Ressource weiterhin zur Verfügung stellen zu können, haben wir Schritte unternommen, um den Missbrauch durch kommerzielle Parteien zu verhindern. Dazu gehören technische Einschränkungen für automatisierte Abfragen.

Wir bitten Sie um Einhaltung folgender Richtlinien:

+ *Nutzung der Dateien zu nichtkommerziellen Zwecken* Wir haben Google Buchsuche für Endanwender konzipiert und möchten, dass Sie diese Dateien nur für persönliche, nichtkommerzielle Zwecke verwenden.
+ *Keine automatisierten Abfragen* Senden Sie keine automatisierten Abfragen irgendwelcher Art an das Google-System. Wenn Sie Recherchen über maschinelle Übersetzung, optische Zeichenerkennung oder andere Bereiche durchführen, in denen der Zugang zu Text in großen Mengen nützlich ist, wenden Sie sich bitte an uns. Wir fördern die Nutzung des öffentlich zugänglichen Materials für diese Zwecke und können Ihnen unter Umständen helfen.
+ *Beibehaltung von Google-Markenelementen* Das "Wasserzeichen" von Google, das Sie in jeder Datei finden, ist wichtig zur Information über dieses Projekt und hilft den Anwendern weiteres Material über Google Buchsuche zu finden. Bitte entfernen Sie das Wasserzeichen nicht.
+ *Bewegen Sie sich innerhalb der Legalität* Unabhängig von Ihrem Verwendungszweck müssen Sie sich Ihrer Verantwortung bewusst sein, sicherzustellen, dass Ihre Nutzung legal ist. Gehen Sie nicht davon aus, dass ein Buch, das nach unserem Dafürhalten für Nutzer in den USA öffentlich zugänglich ist, auch für Nutzer in anderen Ländern öffentlich zugänglich ist. Ob ein Buch noch dem Urheberrecht unterliegt, ist von Land zu Land verschieden. Wir können keine Beratung leisten, ob eine bestimmte Nutzung eines bestimmten Buches gesetzlich zulässig ist. Gehen Sie nicht davon aus, dass das Erscheinen eines Buchs in Google Buchsuche bedeutet, dass es in jeder Form und überall auf der Welt verwendet werden kann. Eine Urheberrechtsverletzung kann schwerwiegende Folgen haben.

Über Google Buchsuche

Das Ziel von Google besteht darin, die weltweiten Informationen zu organisieren und allgemein nutzbar und zugänglich zu machen. Google Buchsuche hilft Lesern dabei, die Bücher dieser Welt zu entdecken, und unterstützt Autoren und Verleger dabei, neue Zielgruppen zu erreichen. Den gesamten Buchtext können Sie im Internet unter `http://books.google.com` durchsuchen.

This is a reproduction of a library book that was digitized by Google as part of an ongoing effort to preserve the information in books and make it universally accessible.

Hydronephrosis, Dr. Alexander, 196
Micturition in women, disorders of, Dr. Horrocks, 670, 698
Nervous disease, some cases of, Dr. Carter, 444
Pneumococcal affections, surgical treatment, Mr. Carmichael, 278,
Pneumonia, treatment of, Sir James Barr, 558, 586
Pneumonia, caseous, Prof. Debove, 34
Pregnancy, extra-uterine, developments and dangers of, Dr. Giles, 612
Optic neuritis and intra-cranial tumours, Dr. Fleming, 58
Sanitation, tropical, Mr. Ross, 332
Strabismus, treatment of, Dr. Story, 222
Ulcer gastric Sir Charles Ball, 170

AUTHORS.
Alexander, Dr., Hydronephrosis, 196
Ball, Sir C., Ulcer, gastric non-malignant, 170
Barr, Sir James, Pneumonia, treatment of, 558, 586
Benson, Mr., Glaucoma, 472
Carmichael, Mr., Pneumococcal affections, surgical treatment, 278
Carter, Dr., Nervous disease, some cases of, 444
Clouston, Dr., Adolescence, mental risks of, 86
Debove, Prof., Pneumonia, caseous, 34
Dempsey, Mr., Antrum, maxillary, empyema of, 250
Fleming, Dr., Optic neuritis, and intra-cranial tumours, 58
Giles, Dr., Pregnancy, extra-uterine, developments and dangers, 612
Horrocks, Dr., Micturition in Women, disorders of, 670, 698
O'Carroll, Dr., Arterial plethora and Bright's disease, 6
Ormsby, Dr., Diseases peculiar to children, 414
Poland, Mr., Fractures and dislocations and skiagraphy, 500
Poynton, Dr., Arthritis, 360
Monro, Dr., Diabetes, 304
Ross, Mr., Sanitation, tropical, 332
Smith, Prof., Floodings, climacteric, 528
Story, Dr., Strabismus, treatment of, 222
West, Dr., Foods and feeding in certain conditions, 644
Whiting, Dr., Acroparæsthesia, 388
Yearsley, Mr., Ear, non-suppurative diseases of, 114, 142

CORRESPONDENCE—FOREIGN

AUSTRIA—
Aniridia congenita, 655
Aorta and syphilis, atheromatosis of, 17
Asthma, isolated, 184
Asymmetry, facial, 345
Autan, 572
Bier's congestion treatment, 46
Bronchus, foreign body in, 71
Cranium, neoplasm of, 98
Cardiac anomaly, congenital, 99
Cardiac defect, 99
Carcinoma, serum, diagnosis of, 153
Cerebro-spinal fluid, 459
Children, protection of, congress for, 682
Cholecystitis, post typhoid, 373
Chondroma and Exostosis, 709
Chromaffine system, 486
Cirrhosis, hepatic, 400
Diabetes, 572
Digital malformation, 291
Disinfection, 709
Diuretic medicines, 46
Dysenteric toxin, 235
Dyspnœa, high tension, 152
Eclampsia, ætiology of, 317
Eczema universale, 683
Endocarditis, ulcerative, 127
Epididymitis, gonorrhoic, 515
Epilepsy autopsy, findings in, 572
Epiphysal multiple separation, 400
Exostosis cartilagenous, 540
Extremities, gangrene of, 127
French visit, 682
Fungoid multiple swellings, 345
Gall bladder and cholesterin, 18
Gangrene from ice-bag, 373
Gangrene, pulmonary, 600
Giant, infantile, 71
Glycosuria, 263
Hæmolysis, 629
Hair quills, 572
Hermaphrodites, pseudo, 399
Huhnerpest, 18
Idiocy, myxo-, 171
Intestinal infection, 46
Invagination, intestinal, 426
Leprosy, 235
Leucocystosis, serum treatment, 459
Ligaments, peritoneal pseudo, 600
Lupus-pernio, 540
Lupus vulgaris, exulcerans, 514
Lymphates, infection by, 427
Mammæ carcinoma, 655
Mammæ cystadenoma, 46
Metabolism and Rontgen rays, 18
Mongolism, 572
Necrosis phosphoric, 540
Neuritis, optic, 317
Ostetis fibrosa, 235
Otetus, temporal abscess from, 513
Ozone in surgery, 600
Paralysis of lower extremities, 514
Parotitis, recurring, 127
Percussion, Marzonus' theory of, 184
Pericardium, heart surgery, 513
Perstasis papulosis, 210
Pertusses and bacillus, 629
Petyriasis lichenoides, pruniens 17
Puerperal diseases, therapy of, 600, 709
Puerperal fever, surgical therapy of, 683
Rheumatism, chronic, and fibrolysin, 514
Rhinolith, 514
Right hand, contractions in, 486
Rontgen apparatus, 235
Sarcoma, and morbus basedowii, 373
Sarcoma, removed by torsion 373
Scoliosis, 540
Stenosis, broncho-, 127
Stomach, perforation healed, 17
Syphilis, maligna præcox, 709
Syphilitica osteitis, 71
Tæmia cucumerina, 290
Tetany, 263
Tetany, and adrenal bodies, 71
Tetany, infantile, 427
Teeth, artificial, accident, 210
Thorax, funnel-shaped, 263
Thyroid epithilial corpuscles, 655
Tick fever, 427
Trichonodosis, 46
Ulcers, Rontgen ray, 400
Uria, indigo, 71
Urine and body temperature, 184
Valgus and pes-varus, functional treatment of, 291
Vara crura, 571
Variola, theory of exanthum in 317

FRANCE—
Alopecia, in women, 151
Appendicitis, treatment of, 261
Asthma, cardio-sclerosis, 343
Biliary cirrhus, 45
Boils, treatment of, 97
Cardiac disease, digitalin in, 681
Colitis, entero-, 344
Collargol, injection of, 315
Death, sudden causes, 290
Digestive tract, hæmorrhage of, 261
Erections nocturnal, 426
Febrik diseases, ice over the heart in, 654
Grippe, treatment of, 654
Hæmorrhage in disease, 398
Heart disease, treatment of, 125
Infants, crying of, 512
Influenza epidemic, 69
Ions, treatment by, 315
Laryngitis, tuberculous, 151
Lymphadenoma of neck, 70
Neurasthenia, 16
Nipples, sore, 571
Paralysis, diphtheritic, treatment of, 681
Paralysis, General, treatment of, 538
Paraphimosis, 571
Peritonitis, tuberculous, 70
Phthisis, first signs of, 289
Phthisis, treatment of, 599
Pleurisy, treatment of, 484
Pulse, slow, 97
Sciatica, 261
Smoking, 261
Suppuration, abortive, treatment of, 539
Sweating, treatment of, 208
Tinea capitas, 457
Tuberculosis, external treatment of, 512
Tuberculosis, pulmonary, sure sign of, 654
Typhoid fever, treatment of, 233
Uræmia, treatment of, 425
Veins, varicose 570
Vomiting, treatment of, 627
Warts, treatment of, 425
Writer's cramp, 485
Zona, treatment of, 16

GERMANY—
Abdomen, retention of foreign body in, 262
Abscesses, splenic surgery of, 571
Addison's disease, 654
Albuminuria, orthostatic, 98, 152
Anæsthesia, lumbar, 628
Aneurysm, arterio-venous and arterial, 571
Appendix, vermiform, primary cinoma of, 708
Bergmann, Prof. von, death of, 708
Berlin, infectious disease in, 234
Bladder, paraffin, calculus of, 599
Brain, blastomycosis of, 654
Cancer inoculation, 539
Cardiac diseases and accidents, 316
Chest diseases in children, 152
Chloroform, cases of late death from, 426
Diphtheria, 459
Diseases communicable, campaign against, 262
Disease, psycho-reflex symptoms of, 426
Ear diseases and life insurance, 372
Epilepsy, opium-bromine treatment of, 183
Exophthalmus, pulsating, 571
Gall-bladder, true and false diverticula of, 628
Goitre and its treatment, 16
Hæmatomyelia, 152
Heart, surgery of, 222
Hepatic duct, rupture of, 71
Infants, natural feeding of, 234
Influenza, encephalitis, 183
Kidney, horseshoe calculus of, 708
Labium, tuberculous ulcer of, 426
Lipoma, intestinal, spontaneous expulsion of, 126
Liver, resection of, 628
Liver, syphilis of, 98
Lysol, antidotes to, 459
Lysol, poisoning by, 209
Menstrual blood, antiseptic action of, 262
Neuralgias, their treatment, 682
Œsophagus, dilatation of, 458
Œsophagus, hæmorrhage from varices of, 708
Optic nerve, atrophy of, 459
Pancreas, fistula in, 126
Pancreas, subcutaneous injurie of, 262
Pharyngitis, meningococcus, 210
Pneumonia contusional, 290, 344
Poisoning by lysol and greosol, pathology of, 485
Puncture, exploratory death after,
Puncture, exploratory, death after, 426
Renal surgery, 70
Schwam-Theodor, monument to, 372
Scoliotica, ischias, 344
Sepsis following pyonephrosis, 210
Skull, sarcoma of, 344,
Speech, loss of, 98
Spleneotomy, successful, 571
Spirochæte, transmission of, 399
Stomach, cancer of, and surgery, 485
Stomach, ulcerated, 210
Tetanus, treatment of, 628
Tuberculosis, 94 nephrectomies for, 399
Tumours, nature of, 599
Typhoid bacilli carriers, 45
Typhoid and milk, 46
Ulcer, Peptic, 98
Ureter, rupture of, 71
Vocal organs, functional changes in 682
Whooping cough, results of, 152

259524

HUNGARY—
  Abdominal section, 18
  Acne, treatment of, 153
  Aorta, ætiology of aneurisms, 263
  Basedowi, Rontgen rays in, 263
  Budapest, milk dispensaries in, 572
  Diphtheria, chronic, 572
  Epilepsy, 572
  Gastric juice, titration, of 263
  Gastro-enteritis, acid, creamless milk in, 263
  Hyperemesis gravidarum, 514
  Lead poisoning, 153,

THE MEDICAL PRESS AND CIRCULAR.

"SALUS POPULI SUPREMA LEX."

VOL. CXXXIV. WEDNESDAY, JANUARY 2, 1907. No. 1

NOTES AND COMMENTS.

Anthrax Report.

THE first annual report of the Anthrax Investigation Board for Bradford has lately been issued. The Board, it may be remembered, consists of representatives of the employers and workpeople engaged in wool-combing, spinning, and manufacturing hair, wool, and alpaca, and, aided by Dr. Eurich as bacteriological expert, they have already arrived at some important conclusions as to infection of workers. During the first year of their existence seventeen cases of anthrax were reported to them, but four of these were doubtful. Out of the thirteen undoubted cases, seven—all persons over forty years of age—were fatal, and six—all persons under thirty-three—ended in recovery. Of the former, all the patients but one were affected by internal anthrax, while the latter all had the disease in external form. All the patients, except the abnormal one mentioned, contracted the disease during the preliminary operations of handling the materials, principally before they had been washed. The most dangerous materials were Persian wool, camel hair, and some kinds of mohair, but the exact varieties which are liable to cause infection has not yet been determined. The majority of the cases occurred among people working for "commission combers," members of the trade who deal with the lowest and least easily worked materials, and many more cases occurred on some "commission combers'" premises than on others'. The Board recommend that certain dangerous kinds of work shall be scheduled, and only combed under the supervision of a government inspector.

Midwives Beware.

THE ways of the book-canvasser are sometimes dark, not infrequently circuitous, and always insinuating, so that it behoves his hosts to scan both him and his goods carefully before "parting." When he has landed his victim with some book which is not wanted, he is exceedingly difficult to catch. An adventurer of this type lately beguiled the police force of a large town into buying an expensive series of books which turned out very differently from what was represented, and though he was vigorously assailed by the law, he escaped scathless. The police are doubtless bigger victims than the humble midwife, but an enterprising gentleman who was tried last week for unloading "The Family Physician" on the midwives of Lancashire on the pretence that it was necessary for them to use it, was found guilty by a jury. The price of this stupendous work was £1 17s. 6d., and it contained only ten pages on the duties of midwives and seven on the management of young children, so that the women who were stupid enough to be taken in by the prisoner did not get much for their money to help them in their work. That is to say, the midwives who are content to remain midwives and do not aim at becoming family physicians. But the latter type is not yet registered off the face of the earth.

Education Committees and Certificates.

THE same want of proper appreciation of the value of medical work is shown in nearly all districts by education committees. These bodies require very properly that a child who is absent from school shall furnish a medical certificate, or be treated as a truant. But in the case of the poor who are unable to pay for a certificate, the committees grant no facilities. It is expected that medical men out of their charity shall furnish what is really their stock-in-trade, namely their opinion, for nothing. On this point a firm stand should be taken. Magistrates who are confronted with a batch of summonses for absence from school cannot convict, if the parents plead the children's illness, and equally they cannot receive this pet excuse unconfirmed. Mr. Harold Wright, the stipendiary for the Potteries District, last month spoke very strongly on the subject, and finally instructed the attendance officer to bring the matter before the County Education Committee. Medical men will be only too glad to give their opinion—when it is adequately paid for.

Another Doctor's Dilemma.

CAN a medical man betray to himself a patient's confidence? This may sound like a conundrum, but it was a practical question which recently stood the test of an action in the Newcastle County Court. A medical practitioner had a chauffeur who was taken ill, and subsequently admitted to the infirmary under his care. On examination the man was found to be the subject of aortic disease, and therefore manifestly unfit to drive a motor-car. The doctor accordingly discharged him on his return from the infirmary, paying him a fortnight's wages. The chauffeur was dissatisfied, and sued him in the County Court, as it turned out unsuccessfully. The interesting medico-legal point is that the doctor, being at once medical attendant and employer, in the former capacity came into possession of confidential information which affected him in the latter. Naturally had he been two persons instead of one, he could not have communicated the facts to the other party, but being a single individual, and human enough not to wish to have his neck broken, he did not retain the chauffeur. Which certainly was the commonsense course, and curiously, therefore, the one endorsed by the Court.

A Happy New Year.

IT is without affectation that THE MEDICAL PRESS AND CIRCULAR can wish its readers a Happy New Year, for while the relationship between itself and many of its subscribers is of the kind that age cannot stale nor custom wither, each year brings it many new and welcome friends, who generously recognise the part it plays in the fields of medical science and medical politics. The change that has been taking place in development of medical knowledge during the last quarter of a century is no more striking than that which has attended the conditions of medical practice, and it is appreciated by all those who are in the position to form a judgment that the lot of the medical practitioner becomes harder every year. The reasons for this state of things are to be found partly in intrinsic and partly in extrinsic circumstances; but the fact which stands out prominently is that it is only by taking up the cudgels himself and entering actively into the contest that the medical man can hope to obtain adequate recognition for his services. The fight is a righteous one, and we believe that the real happiness of 1907 will be found more in the joy of combat than in the partaking of *otium cum* (or *sine*) *dignitate*.

Social Evolution.

IT is now nearly a century since the real struggle between class and class began to show itself in this country, the struggle whose earliest fruits were garnered in with the first Reform Bill, and from a simple conflict between the old territorial magnates and the proletariat, this struggle has gone gradually on till every class in the community has become involved. The great middle-classes which supplied the brains and the energy of the country could not stand aside long, and now almost every section of society, from the House of Lords to the Bricklayers' Union, is fighting to justify the existence of its members. Medical men, who are primarily engaged in the service of humanity and secondarily in the study of the phenomena of health and disease, stood aside from politics as long as they could, but the pressure of events and the gradual process of "squeeze" to which they are subjected has made them feel that there are limits to human endurance. For their own self-respect and the sake of those dependent on them, they know they must struggle against inadequate pay, unfair competition, and ruthless sweating.

Medical Men and Free Calls.

THE practitioners in poor districts, for example, are regarded as fair game for any unscrupulous "bilker" who likes to prey on their generosity, and the newspapers are mostly only too glad to aid any outcry against them. Last week a leading London daily reports with sensational headlines a message from its Birmingham correspondent to the effect that on Christmas morning a poor woman whose husband was taken ill, called on seven doctors, each of whom refused to attend without his fee. It is grossly unfair that such an unconfirmed story should be published in a way to excite prejudice against the profession of medicine. The *Daily News*, the paper in question, does not give a single copy of its issue away without getting its halfpenny, and if a newsvendor had persistently swindled it and its contemporaries, it would refuse to trust him, even if he were ill or starving. In the case under notice, we have no particulars as to the character of the individual, but medical men all know the patient that goes the round of the doctors in a town, and pays none of them. If this man were of that class, the practitioners in question were perfectly justified in referring his wife to the Poor-law medical officer, and, as a matter of fact, there was no difficulty about his treatment, as he was removed to the hospital. But there is a type of paper and a type of individual who find no weapon too much envenomed to use against a medical man.

The Devil and the Deep Sea.

IF there is not venom there is often the most crass stupidity in the way that public bodies treat medical practitioners, and of such a charming instance was given last month by the Llanfrechfa Urban District Council. It appears that Dr. A. W. Hoyles of that district was attending an obscure case of illness which eventually turned out to be one of typhoid. When the diagnosis was established to his satisfaction, he notified the case in due course, but the wiseacres of the Council took it upon themselves to write complaining that he had not notified it earlier. Dr. Hoyles replied, very appropriately, that any ignorant busybody could be wise after the event, and that he had notified the case at the earliest moment he could. On a previous occasion his assistant had notified an infectious case, and because the diagnosis was not confirmed bacteriologically, the Council refused to pay the fee. He felt himself between the devil and the deep sea. A clergyman on the Council is reported to have characterised the letter as "an insult," and he finally proposed and carried a motion that Dr. Hoyles was expected to carry out his duty. A more glaring case of barbarous want of logic it would be difficult to find. The Council acted absolutely illegally in refusing the fee to Dr. Hoyles' assistant, and now they complain when he tries to save their face in a similar case! The Council might well study their own duties under the Act a little more carefully.

LEADING ARTICLE.

THE ANNUS MEDICUS 1906.

THE year that has recently come to a close naturally suggests some sort of a retrospect from the point of view of our medical readers. The researches of modern scientific medicine are so widespread and the energy of investigators so unparalleled, that marked progress can be recorded from all parts of the line. Every now and then the medical world is spurred on to greater effort by the discovery of some fresh fact, such as that of the tubercle bacillus, or of some hitherto unknown force, such as that of the Röntgen rays. On rarer occasions comes the general law enunciated by a Harvey or a Lister. During the past year no very striking discovery has been made. At the same time, it is impossible to say what epoch-making observation may not have been recorded in the vast flood of medical literature that is daily put forth in all quarters of the civilised world. The demonstration of the curative influence of the Röntgen rays in various leuchæmic conditions, for instance, may one day prove the key to a therapeutic advance of first-rate importance. Heart surgery, again, has been the object of gratifying advances; so much so that the surgical treatment of diseased valves might conceivably be brought to some extent within the range of the surgeon's art. An interesting point in anæsthetics has been the increased attention devoted to spinal anæsthesia induced by the injection of stovaine and other drugs into the vertebral canal. Serious operations can in this way be performed painlessly, and there are obvious advantages in the avoidance of so-called "shock" and subsequent vomiting. At the moment it should be carefully noted that a certain percentage of deaths have occurred under this method even in the most experienced hands. Clearly, the last word in surgical anæsthesia has not yet come to us in the shape of spinal anæsthesia. It would be out of the question here to attempt anything like a comprehensive review of the scientific advances of the year 1906. Some of its most interesting work has been performed in the study of tropical diseases, a field that has furnished the inspiration, as in some instances it has unhappily proved the grave, of some of the best men in the profession. The past twelve months has added greatly to our knowledge of the pathology and treatment, chiefly preventive, of that scourge of the tropics known as sleeping sickness. Nothing of great importance has been achieved in the war against tuberculosis. A significant fact, however, is the onslaught that has been made in some quarters on the policy of building palaces for the reception of tubercular patients. The vast cost of such institutions limits to a disastrous extent the number of poor patients that can be taken in. It seems likely that in future the sanatorium building will be of a simple and inexpensive nature. So far as the highly ingenious "opsonic index" of Sir A. Wright is concerned in gauging the extent of the disease and the progress of the individual under medical treatment, the past year cannot be said to have placed his method on any securer footing as a practical aid to the physician. This negative fact is noteworthy in view of the costly, tedious, and highly technical nature of the method. The interest in the excessive child mortality that forms so serious a blot on modern public health administration has been sustained during the past year. The original experiment of the Mayor of Huddersfield, who effected a great saving of infant life by offering a premium upon the babies born during his year of office, provided they survived twelve months, has furnished an important object lesson as to the ease with which a vast deal of this lamentable waste of life can be prevented. This example has been already followed in various parts of the United Kingdom. A great deal of mortality amongst infants is directly due to the use of patent medicines, such as teething powders and soothing syrups. It is clearly within the power of Government by legislation immediately to strike out that particular part of the causation. In the case of babies, as of grown-up persons, the indiscriminate use of remedies, often potent and poisonous, undoubtedly leads to a vast amount of injury to health and loss of life. In spite of many years of remonstrance on the part of the medical profession, the game goes merrily on, and is even sanctioned by the Government in the shape of a paltry patent medicine stamp. The sale of worthless nostrums under the ægis of official sanction not only inflicts a terrible and incessant injury upon the King's subjects, but also trenches upon the field of legitimate medical practice. On these grounds, during the past year the MEDICAL PRESS AND CIRCULAR has conducted a vigorous campaign against the patent medicine trade and against the journals that insert their lying and fraudulent advertisements. We are glad to see that the Treasury has at length come to realise its responsibilities in the matter, and has secured the conviction of notorious electrical and other quacks in various parts of the Kingdom. Were the Treasury to accept the logical consequence and prosecute newspapers who publish the obviously lying advertisement whereby these vampires of society secure their victims, then the trade would receive its quietus within a short space of time. In other directions there are signs that medical men generally are waking up to the necessity of self-protection. They have brought pressure to bear upon the lay managers of medical charities, and a conference of delegates was held in London last December to consider the question of hospital abuse. The attempt to thrust a number of cut-and-dried resolutions down the throats of the conference was resented by the delegates, and the matter was left for a second annual meeting to consider. The incident shows that determined wire-pulling is still a danger ahead in medical politics. Among other things the meeting was asked to give its unqualified approval to the pay system in hospitals, and generally to disapprove of small and special hospitals. Sir Henry Burdett, who moved the resolution, is notoriously in favour of both those views. It is high time, however, that medical men learned to think and act for themselves, apart from professional philanthropists and presidents of medical corporations. The General Medical Council has not taken any very important action during 1906. The recent election of Direct Representatives resulted in the unseating of three old and tried members of the Council. We cannot do more than mention army medical reform, medical inspection of schools, and the inclusion of many industrial diseases within the Employers' Liability Act, each pregnant with possibilities so far as the profession is concerned. With respect to the changes in the form of the MEDICAL PRESS AND CIRCULAR, we have solid reason to know that they have secured the approval of a large and increasing circle of readers, especially with regard to the foreign clinical lectures, some of which have come from the most distinguished medical authorities in Europe.

CURRENT TOPICS.

A Journal for Tuberculosis.

It is with great pleasure that we welcome a new contemporary, the *British Journal of Tuberculosis*, the first number of which has just appeared. The growing interest which the subject of tuberculosis has aroused of late years among medical men and the public is a phenomenon pregnant with possibilities for the future, and vast increase in pathological and clinical knowledge concerning the disease has made the publication of a special journal devoted to its consideration not only a desideratum but an absolute necessity. Such a journal, however, needs careful editorial handling and strong medical support if it is to be what it should aim at being, a trustworthy source of scientific information on tuberculosis, and not a mere *rechauffé* of work given elsewhere. The *British Journal of Tuberculosis* is under the capable editorial control of Dr. T. N. Kelynack, and if he succeeds in keeping his other numbers up to the standard of the one that lies before us, a long and useful career is assured. Besides the usual editorial matter, this number contains two capital articles, "A Retrospect," by Professor Clifford Allbutt, written in his happiest strain, and "An Anticipation," by Dr. R. W. Phillip, of Edinburgh, whose motto is *L'Avénir est aux Audacieux.* These are succeeded by contributions by Sir Richard Douglas-Powell, Dr. Byrom Bramwell, and Sir John Moore, discussing the Care and Control of the Consumptive Poor in England, Scotland, and Ireland respectively. Four original papers on various questions connected with tuberculosis follow, the authors of which are Sir Lauder Brunton, Sir Hermann Weber, Sir Samuel Wilks, and Dr. Francis Hare. Needless to say, they are all worth study. Illustrated descriptions of three typical sanatoriums—the King Edward VII., the Brompton, and the East Anglian — are given, as well as some account of various health stations for the tuberculous. Finally, a long list of books on tuberculosis and cognate subjects is reviewed, and careful notices of special appliances and preparations for the consumptive are supplied. The journal is well got-up and beautifully printed on really good paper by the publishers, Messrs. Baillière, Tindall and Cox. As it is to appear quarterly, and the subscription is only five shillings, no doubt the *British Journal of Tuberculosis* will soon have a large *clientèle* of admirers and supporters.

Army Medical Changes.

There have been many grumblers of late as to the promotion, and passing over for promotion, of the more highly-placed officers of the Royal Army Medical Corps. This, perhaps, was only to be expected in a service that had been reconstituted under a new head, but we are not in a position to say how far such complaints are substantial or not. However, still further changes have now been introduced into the corps organisation, and we hope they will work to the satisfaction of all. In the first place, the Army Hospital and Sanitary Committee, whose existence was obviously superfluous, has been done away with, and its functions will now be assumed by the Advisory Board. This Board has been reorganised also, and will consist of the Director-General, as chairman, the Deputy-Director-General, a civilian sanitary expert, a civilian physician, a civilian surgeon, a civilian physiologist—a rather odd choice—a military expert in tropical diseases, a Royal Engineer, and the President of the Indian Medical Board. The Board, thus manned, will advise on all medical questions affecting the soldier, upon questions of hygiene, training, clothing, and so on, upon hospital organisation, upon matters affecting the examination and admission of candidates to the service, and upon the education of officers. The promotion of officers is to be recommended by the Director-General and the Surgeon-Generals serving at home to the Selection Board, and an Inspector-General of Hospitals and Sanitation is to be appointed on the staff of the Inspector-General of the Forces. The effect of these changes, if carried out in the spirit that has dictated them, will be widespread and profound, and at present we can only say that we welcome them heartily.

Meat Essence Dangers.

People who favour tinned meat essences for the sick will do well to read the report just presented to the Local Government Board by Dr. G. S. Buchanan and Dr. S. B. Schryver. Information was laid before the Board by certain British manufacturers of tinned meat essences that consignments of their goods which were being returned to this country after the South African War, were in an unsatisfactory state. Some thousands of tins were therefore seized at Southampton by the medical officer of health, and examined by Dr. Buchanan. The contents were found, in many instances, to have undergone certain changes, the chief of which were that the jelly had become fluid, and that this fluid was turbid and dirty yellow in colour. Analysis showed that these changes were due to the action of the meat essence on the metal of the receptacle, which resulted in a certain amount of the tin being dissolved and later precipitated, either as a double salt of a meat base or as a metallic salt of an organic acid. In one case the quantity of tin discovered was as high as 21.87 grains to the pound, though the average was only between one and a half and two grains per pound. It is said that the manufacturers, for commercial reasons, do not in the ordinary way issue more than small quantities of their essences at a time, and that the chance of a purchaser getting an old tin is practically *nil*, but at the same time it will be advisable to notice if the contents of such tins are ever fluid, and, if so, to discard them. Perhaps the manufacturers will see their way to providing glass or other innocuous receptacles in the future.

The Survival of the Unfit.

It is a curious reflection that our advancing civilisation tends to secure the survival of the unfit rather than of the fit. The utmost care, for instance, is expended over the nurture and the tending of degenerates and of cripples, while whole armies of able-bodied men, women, and children are permitted to pass their lives in a state of semi-starvation and squalor. Sooner or later it may come about that reasoning mankind will bring stern logic to bear upon the question, and will decide to protect the producer rather than the non-productive cumberer of the earth. For what rational being could seriously contend that as a sensible nation we are justified in starving the fit in order to keep alive individuals whose survival is of doubtful benefit either to themselves or to the community at large. At the same time we cannot endorse the extreme view adopted by Dr. Trotter, Medical Officer of Bedlington District Council, who has the courage to speak out his mind on the matter. "When one finds the Legislature," he recently remarked, "passing laws for the benefit and education of feeble-minded, defective children, one is inclined to wonder whether we are not a nation of fools, whether we should not benefit the nation more if we followed the custom of the ancient Spartans, and stamped such types out altogether."

Overcrowding in the Central Telegraph Office.

So much has been done in one generation to improve the conditions of labour, that one would hope that in Government employment, at least, work might be carried on under favourable circumstances. So far, however, from Government being a model employer, in certain departments of State service there is evidence of sweating and other grave abuses. A great evil was made public by question and answer in the House of Commons at the end of session. Sir John Bethell drew attention to the serious over-crowding in the telegraph school at the Central Telegraph Office, and the Postmaster-General was unable to deny the charge. It would appear, moreover, that several months ago the accommodation was reported insufficient by the medical officer, but that nevertheless no steps were, until quite recently, taken to acquire more space. It is intolerable that young men and women should be crowded together in a manner dangerous to health in a Government office, and the public has a right to insist that its employees should be fairly treated. Charges have more than once been made that phthisis is unduly incident on telegraph and post-office workers, and it is scarcely matter for wonder if such be the fact.

Infantile Mortality.

Following on the heels of the Huddersfield and other municipal experiments in baby-rearing comes the report of Mrs. Boileau on the results of her work in the capacity of visitor to the Wakefield Sanitary Aid Society. It is not surprising to find that lady echoing the words that we have over and over again uttered when discussing the prevalent excessive infantile mortality. She forcibly points out that the mortality is only a measure of the injury inflicted upon the survivors, and that for one baby that succumbs to any particular form of error there are three or four who struggle through more or less maimed for life, either as ricketty cripples, or with the beginnings of chronic lifelong disease implanted in them before they are out of their cradles. Mrs. Boileau confirms the fact that the greater part of the mortality is due to the sheer maternal ignorance. The only excuse conceivable for their error is that they have never had any opportunity before matrimony of acquiring any knowledge of the proper methods of rearing their offspring, and have had no means of gaining any information when motherhood has come upon them. Many babies are killed owing to the belief that breast milk does not in itself furnish enough nourishment. Improper foods of all kinds are commonly administered, and babies die from intestinal disturbance thus provoked—virtually poisoned. By mere diffusion of necessary information on the practical effect of baby-rearing a great reduction in the death rate has been brought about at Wakefield as at Huddersfield. These experiments suggest how vast a field for social reform lies open to private effort, and how many of the sores that afflict society of to-day, to cure which new legislation is constantly clamoured for, might be dealt with by similar means, the efficacy of which has been demonstrated in the two Yorkshire towns, which have set so good and practical an example.

PERSONAL.

H.M. the King has given £450 out of the State Apartments Fund of Windsor Castle to the building fund of the new King Edward VII. Hospital, opposite the Cavalry Barracks, Windsor.

Dr. Slater has been authorised by the Bradford Guardians to inspect the system for treating ringworm by Röntgen rays in operation at the London Hospital.

Sir John W. Byers was lately presented by his colleagues of the Royal Victoria Hospital, Belfast, with a silver rose-bowl, on the occasion of his receiving the honour of Knighthood.

Mr. and Mrs. Bischoffsheim have given the munificent donation of £40,000 to the Imperial Cancer Research Fund on the occasion of the celebration of their golden wedding. Stock for this amount has now been transferred to the trustees of the fund.

Professor Kuenen, of University College, Dundee, has been appointed to the newly-established Chair of Physical Chemistry in the University of Leyden. He is a graduate, a gold medallist, and Ph.D. of Leyden University, and worked with Professor Ramsay in University College, London.

On Friday last, Mr. O. H. Fowler, of Cirencester, who retired from active professional work at the close of the year, after over forty years' devoted labour, was presented with an illuminated address, bound in book form, with the signatures of about 350 contributors, together with a very handsome and massive silver-gilt double-handled cup, of rich workmanship, of the period of George II., the date being 1752. The ebony plinth bore the following inscription: "To Oliver Humphrey Fowler, M.R.C.S., on his retirement after forty years' practice at Cirencester, the gift of many friends, who will always gratefully remember his skill, judgment, unfailing kindness, and attention.

A CLINICAL LECTURE

ON

ARTERIAL PLETHORA AS AN EARLY SYMPTOM IN CERTAIN CASES OF CHRONIC BRIGHT'S DISEASE.

By JOSEPH O'CARROLL, M.D., F.R.C.P.,

Physician to the Richmond, Whitworth, and Hardwicke Hospitals.

GENTLEMEN,—I have constantly impressed upon you that in examining the pulse at the wrist you should take note of five things, namely, the rate, the rhythm, the size or fulness, the tension or pressure, and, lastly, the character of the arterial wall itself. The first you estimate by counting the number of beats in the minute; the second means that you look for evidence of irregularity either as to rate or volume or force in the pulse; and it sometimes takes a good deal of skill and concentration of attention to discover such irregularities, although the grosser forms are easily appreciated.

The size or fulness of the radial artery is usually taken as an index of the fulness of the peripheral arterial system as a whole; though experience, physiological and clinical, teaches us that special arterial areas may be dilated and over-full while the remainder of the system is normal or below normal in fulness. The cases I propose to show you to-day illustrate the necessity of attention to this factor in the pulse. They will be examples of the full pulse combined with high tension, a condition which contrasts strongly with the full pulse of low tension, usually met with in the early stage of the continued fevers as well as many other conditions.

Arterial tension has within the past quarter of a century assumed a position of continually increasing importance. Many instruments have been invented for its estimation; all, or almost all of them, measuring the tension in any given artery as the amount of pressure necessary to extinguish the pulse in it. In clinical work it is not always convenient to use mechanical devices for such a purpose. Their application takes a good deal of time, and the reliability of the result is by no means proportionate to the time and labour employed by the physician; for between the imperfection of the apparatus itself, the personal factor of the observer, and the frequent agitation of the patient under an unaccustomed manipulation, there is large room for error. I do not desire to under-value such instruments of precision; far from it. You have seen me use the Riva-Rocci manometer frequently; but you will have observed that I rarely attach importance to the first or even the second observation on a nervous patient. In any case, we cannot always have a blood-pressure instrument with us, but we can always have with us two or three well-trained fingers. And the well-trained finger is almost always capable of informing us whether a given radial artery is decidedly above or below the limits of normal tension. Applying the index and middle fingers of the right hand to the right radial artery of the patient, one slowly presses down the index till the middle finger ceases to preceive the pulse; the force which one is conscious of having to use for that purpose is the measure of the radial tension. Occasionally on account of a back flow through the *superficialis volæ*, or other communicating artery a pulse may be felt in the radial when the index has manifestly occluded it above. It may then be necessary to occlude the artery below with the ring finger. Then raising the index gradually till the pulse wave from above is again felt, and again pressing it down till the pulse barely disappears, one gets from the index as before an impression of the minimal pressure necessary to annihilate the pulse; and this may be taken as the arterial pressure in the patient's radial.

Finally, one gets an estimate of the condition of the arterial wall itself, whether it is thickened or hardened, by rolling the artery across the lower end of the radius under the fingers pressed tightly against that bone. This manœuvre is necessary because a thick artery or an atheromatous one may easily be mistaken for "a strong pulse," unless one realises that a good pulse by no means implies that the emptied artery itself should be perceptible at all. Unless in very thin persons, the actual tube of the radial artery should not be at all perceptible to the fingers. When it is perceptible, no matter how young the individual, the artery is either diseased or has undergone a senile degeneration. I say senile degeneration because the ordinary healthy, active man tends to get more and more perceptible arteries as he gets beyond fifty years of age. In the labouring classes the healthy individual may show hardening of the arteries long before that age; and premature hardening of the arteries may show itself also in persons who devote too much attention to athletics, especially those forms of physical exercise such as prolonged bicycle-riding which demand long continued muscular exertion. Long continued mental exertion may produce the same result, especially that nervous tension which one now and again sees in energetic and successful commercial men; or the long continued and anxious, though not often proportionally successful existence led by our own profession.

I have recapitulated these commonplaces this morning because I propose to show you two cases in which they are highly apposite. You will remark in both of them that the radial tension is above that which your experience has taught you to be normal. But you will also be struck with the very large volume of the arteries of these two cases. As it happens, both these men occupy a level in life distinctly higher than the labouring class, from which most of our hospital patients come.

Our first case, J. C. He is manager of an important wholesale and retail drug shop, where he superintends not merely the constant counter work, but a large amount of country business. This latter part of his work takes him away for about two days a week, which he spends rushing from town to town getting orders for his firm; always with the nervous tension begotten of the anxiety to do as much business as possible in each town, and at the same time not to miss the train for the next. He is 47 years of age, married, has healthy children. There is no reason to suspect syphilis, and it is denied; but, of course, one cannot positively exclude it. He takes alcohol, rarely, and in extremely moderate quantity indeed. His medical history, for much of which I can vouch personally, as I have attended him frequently before his admission to hospital, is as follows: About five years ago he began to suffer from fronto-occipital headaches. A year later he had an attack of bleeding from the nose which lasted on and off for four days. Two years ago I saw him first. He complained to me of dyspeptic symptoms, flatulence, and some tendency to constipation, of headache, and of this symptom more than any other, that any excitement, such as that due to business worries, makes him feel as if he should lose his mental control.

In appearance he was above the average height, spare, but not thin, had perhaps an excess of colour in his face, but looked on the whole a healthy enough man. The radial arteries, and, indeed, all the arteries within reach of investigation, seemed somewhat too perceptible when rolled under the fingers; but what was much more striking was their large size, in fact, their undue fulness. The tension was somewhat in excess, and the second sound at the base of the heart was accented. The cardiac area was not markedly enlarged, but the precordial movement was unduly evident. The urine was of specific gravity 1,018, and showed a faint trace of albumen, not enough to make ¼ per 1,000 in Esbach's tube; one or two doubtful casts were found.

Exactly a year later, not having seen him for some months, I found a systolic murmur at the base of the heart. The second sound was more decidedly accentuated, and it had taken on a ringing or metallic character. From that onwards he suffered more and more from paroxysms of cardiac excitement, with dyspnœa, forcible palpitations, and extreme and acute mental anxiety; and these paroxysms usually attacked him late at night, some hours after his work was finished, and about the usual hour for going to bed, or shortly after he had gone to bed. Four times I saw him in these attacks, and on three of these occasions I bled him from the arm to the amount of half a pint, producing almost immediate relief, and a quiet, restful night. About four months ago he first gave evidence of a diastolic basal murmur, and since then he has developed into a more or less commonplace case of aortic regurgitation, with concurrent chronic interstitial nephritis.

To-day you see nothing very remarkable about the case, but you will notice the unusually large throbbing arteries with the typical Corrigan's pulse; and I may inform you that since his admission a fortnight ago he has had two or three attacks of nocturnal dyspnœa. You will find all the evidence of cardiac hypertrophy; while the urine, with specific gravity varying between 1,016 and 1,012, shows about one part per thousand of albumen, and the daily output of urea is under 250 grains. One would now offer the diagnosis, and rightly, of chronic contracting kidney with aortic regurgitation. He is quick in intelligence, and in his general vital reactions; but there is no doubt that he is suffering from what I may call sub-uræmia; and the prognosis is very bad indeed.

The second case you have already seen once or twice, so I shall not go into the history at great length. He is a curate, aged 45, with a large family and small means, has led a temperate life so far as the world's luxuries go, but has come in for more than his share of its anxieties. He has had to do a great deal of work, for the most part conducting a service in one part of his parish in the morning and at a distant part in the evening. The *res angusta domi* has always weighted down his shoulders. Brought in to us a month ago, apparently in a sub-comatose apoplectic condition, it was difficult to make out any special paralysis. Both knee jerks were excessive, but Babinski's toe-extension sign was not well marked. The urine was found to contain about one per thousand of albumen. The arteries were excessively large, and throbbed with undue force; the precordial cardiac movement was excessive; the second sound was unduly loud, and I suspected at the time a faint whiff of a diastolic murmur. So urgent was the condition of the patient, and so markedly did the arterial plethora compel our attention, that at my first visit I bled him to the amount of twelve ounces, or more than one-third of a litre. There was no marked improvement, so I directed our assistant physician to bleed him again before nightfall. In the evening ten ounces of blood were removed. Next day a marked change was evident. Some consciousness had returned, he moved his limbs freely by way of making himself comfortable. Within a few days the attack had almost completely passed away. Now there is little to attract your attention except that, like the other case, he has very large, full arteries, no longer, however, of high tension; a distinct aortic regurgitant murmur, and about ¼ per thousand of albumen in the urine. He is no doubt a chronic nephritic case, and the prognosis is none too good. But he may be spared for a year or two if he can take things easily and is careful to keep down his arterial plethora as much as possible.

As I said to you earlier, I have chosen these cases to illustrate the chronic full pulse. You may fairly tell me that I am showing you two cases of chronic Bright's disease. That is true enough, but I may fairly rejoin that you are thereby merely affixing a generic label, while I prefer a more specific one. As a matter of fact, it has long been a matter of controversy as to whether chronic Bright's disease is primarily due to a vascular or a renal lesion. So far as these cases go, having in view the very early prominence of the arterial plethora, I think they suggest a vascular origin. As to the cause of the vascular mischief—the vascular hypertrophy, as it may be regarded—we can for the present hardly get further than suggesting some chronic toxic condition of the blood itself, due, no doubt, to a complex of causes, some of them external to the body and begotten of social habits and obligations, the others intrinsic and referable to faulty metabolism in the tissues, and more especially in the liver and gastro-intestinal tract. To just the same causes, no doubt, one would refer the degeneration in the kidneys where such degeneration seems to be the primary event. And these reflections bring us back to the fundamental fact that the kidneys may be regarded as a part of the circulatory system. Of the bulk of blood which leaves the left ventricle a part is delivered into the veins, a part into the lymphatics, and a part is filtered away by the kidneys. If any set of causes conspire to fill the arterial system to harmful excess, the brunt of such harm must be borne by either the heart or the arteries or the kidneys, and ultimately by all of them. Hence arise hypertrophy of the heart, hypertrophy of the arteries, and no doubt for a time if not hypertrophy at least hyperæmia, and ultimately cirrhosis of the kidneys. When one of these results anticipates the others it is probably due to some selective action of the toxins circulating in the blood, or, as I prefer to think, to some selective defence residing in the organism calculated to oppose as far as possible the circulatory toxins. In the first case I showed you there is very little doubt but that the arterial changes came first; they were gross and unmistakable for years before any cardiac or renal changes became prominent. The sequence of cardiac involvement has occurred almost under our eyes. The systolic basal murmur was at first the result not of aortic valve mischief, but of atheromatous changes in the aorta above the valves. These extended within the past few months downwards to the valves till they became calcareous or sclerosed, and ultimately unfit for that delicate apposition which prevents regurgitation from the aorta into the left ventricle. The renal mischief, decided as it is even at present, is not the most prominent or most urgent lesion; for although the excretion of urea is much below the normal, it is to be remembered that his diet has been reduced to as low nitrogenous limits as possible.

In the second case, although I am not as well acquainted with his medical history, I find circumstantial evidence in favour of the vascular origin of what is no doubt a terminal chronic Bright's disease.

I am not for an instant contending that this is the sequence of events in all cases of chronic Bright's disease; but rather for the view that the primary change is in one set of cases in the vascular system, in another group in the renal filter, and sometimes perhaps, though very rarely, in the heart. If we accept this view we shall not be committing ourselves to any too narrow conceptions; and we shall at least be interested in classifying our cases of chronic Bright into those with early marked thickening of medium-sized, or even small, arteries, and those which for a considerable period present arteries which are very large and full, which may for a long time have only intermittent high tension, and in which the parietal degeneration tends to be central, that is in the aorta, rather than peripheral, in the radial and other small arteries.

Granted this distinction, some indications for treatment arise from it. In the more common arterio-sclerotic form, without any great plethora, the treatment can be little more than dietetic, and perhaps in less measure medicinal. Under this latter head comes the use of purgatives and of the vasodilators, the nitrites especially. In the cases in which arterial plethora is characteristic dietetic measures are even more valuable than in the other form; brisk purgation is useful, but vasodilator drugs are practically valueless. In my first case they sometimes aggravated the paroxysmal distress; they never substantially relieved it. In these cases one may with safety aim at a reduction of the actual gross quantity of blood in circulation; and I am satisfied that no measure is so effective and so harmless as periodical venesection.

☛ Note.—*A Clinical Lecture by a well-known teacher appears in each number of this journal. The lecture for next week's issue will be by Dr. Robt. Alex. Fleming, F.R.C.P., Lecturer on the Principles and Practice of Medicine in the Edinburgh Medical School, Assistant Physician to the Edinburgh Royal Infirmary, the subject being "Optic Neuritis and Its Relationship to Intercranial Tumours."*

CLINICAL LECTURES FOR 1907.

We have already been favoured by promises of Clinical Lectures from the following Hospital teachers and Post-Graduate Lecturers:—

Wm. Alexander, M.D., R.U.I., F.R.C.S., Lecturer on Clinical Medicine, University of Liverpool.
Sir C. Ball, F.R.C.S.I., Regius Professor of Surgery, Dublin University.
Sir James Barr, M.D., F.R.C.P., Lond., Physician, Royal Infirmary, Liverpool.
Arthur H. Benson, M.A., Dub., B.A., F.R.C.S.I., Surgeon, Royal Victoria Throat and Ear Hospital, Dublin.
John Bland-Sutton, F.R.C.S.,Eng.,Surgeon to the Middlesex Hospital and to the Chelsea Hospital for Women.
Sir John Byers, R.U.I., M.A., M.D., Professor of Midwifery and Diseases of Women and Children, Queen's College, Belfast.

ORIGINAL PAPERS.

THE "ORGANIC" TREATMENT OF GASTRO-INTESTINAL AFFECTIONS.

By Prof. G. A. WEILL, M.D.,
Physician to the Paris Hospitals.

(*Specially reported for this journal.*)

Since the bacterial origin of so many diseases gained universal admission, one of the principal objects of medical research has been to combat the disease-producing organisms, introduced from without, which gain a footing in the body, and cause more or less serious functional disturbance. The surgeon takes every conceivable precaution to avoid pathogenic organisms when called upon to open possible doors of entry in our first line of defence, which is the skin, while the hygienist disinfects dwellings and recommends sterilisation of the food in order to ward off attacks *via* the lungs and stomach.

But apart from the bacteria from without, there are immense numbers of micro-organisms which make the human organism their *habitat* after the first few hours of life, and they live and multiply on what they find there. The most important of these organisms are certainly those which people the digestive tract. To begin with, the mouth is inhabited by a whole series, to describe which would require an article to itself. Even the stomach, in spite of the fact that it contains an acid distinctly unfavourable to their growth, has its distinctive flora. The small intestine is comparatively free from micro-organisms; but the larger intestine is the happy hunting-ground of a large number of micro-organisms belonging to the group of bacilli, as well as micrococci and spirillæ.

Notwithstanding an immense amount of research, we are not yet in a position to enumerate the varieties and distinctive features of the numerous micro-organisms that inhabit the digestive tube. They are said to be extremely prolific, the number of microbial units figuring in billions

It was some time before medical science took cognisance of this microbial population, but recent advances in bacteriology have brought them within the sphere of our attack. Physicians specially addicted to the study of disease in children were the first to investigate the microbial growths met with in the alimentary canal. The frequency of intestinal diseases in the young led them to seek for micro-organisms capable of explaining their causation. Although these researches cannot as yet be said to have yielded very tangible results, we are justified in arriving at the conclusion that intestinal microbes play an important part in our existence, and that it is incumbent upon us to take them into account.

It has been shown that, if not all, at any rate a certain proportion, of the micro-organisms inhabiting the large intestine are unquestionably pathogenic. Among them we find anærobic bacilli that set up butyric and putrefactive fermentation, with the formation of substances productive of mischief to the human organism. These researches, indeed, have given birth to the theory of auto-intoxication, due to the products of intestinal microbes, and medical science has been directed to the discovery of the means of destroying these intestinal microbes without harm to the host. But the problem presented too many difficulties ; indeed, it is well nigh insoluble, because microbes in general are much more resistant to antiseptics than are our own tissues.

Under these circumstances we have had to look elsewhere for the means of preventing the multiplication of this pathogenic flora. It has long been known that the fæces of young breast-fed infants are devoid of the usual fæcal odour, and these fæces contain but a very limited microbial flora. We know, on the other hand, that milk keeps good outside the organism much better than other albuminoid substances, such as blood, meat, eggs, &c., which become decomposed in a comparatively short space of time. Milk, instead of decomposing, curdles, although retaining an agreeable taste and smell—in fact, milk undergoes lactic acid fermentation, which protects it against the germs of putrefaction. On the strength of these observations, lactic acid has been introduced into therapeutics as a remedy for the intestinal disturbances of children and adults. The results of the treatment having proved eminently satisfactory ; attempts have been made to implant lactic germs upon the intestinal soil. These lactic germs, living among the other microbial inhabitants of the alimentary canal, secrete their characteristic products, lactic acid and others. These products hinder the development of the butyric and putrefactive germs, thus getting rid of a fertile source of disease.

Many diseases are associated with fœtid stools, due to the presence of putrefactive organisms, and we know, on the other hand, that fæcal stasis, consequent upon constipation, facilitates intestinal putrefaction, and permits the absorption of putrefactive toxins. Lactic fermentation, taking place in the very bosom of the organism, enables us to combat preventively all diseases of the intestines, vascular system, kidneys and skin due to this cause.

Pastoral peoples who breed cattle, and make extensive use of curdled milk (negroes of Central Africa, Arabs, &c.) usually enjoy excellent health and live to a ripe old age, and we are justified in attributing their longevity in part, at any rate, to the freedom from intestinal complaints associated with intestinal putrefaction.

Modern bacteriology has turned all these data to useful account, and has evolved a practical application therefrom. Instead of introducing the sour milk treatment, a method has been devised by Professor Metchnikoff for the preparation of curdled milk by the aid of specially-selected lactic ferments. Two species have been chosen in particular, one known as the Bulgarian bacillus and the other as the strepto-bacillus or paralactic bacillus.

In order to purify the intestinal canal of its ordinary microbial contents, it occurred to us to introduce pure cultures of these two micro-organisms in the form of a mixture now knownas lactobacilline. These cultures can be prepared either with milk that has been boiled, sterilised, or thoroughly pasteurised, or with infusions of malt. Dr. Teissier, of Paris, has obtained remarkable results in the treatment of intestinal diseases by the administration of pure cultures of the paralactic organism prepared in peptonised beef tea. This method of treatment has now been before the profession for several years, and has proved very efficacious in all affections dependent upon, or associated with, intestinal putrefaction and butyric fermentation.

FURTHER EXPERIENCES IN THE USE OF AN ANTISTREPTOCOCCUS SERUM IN GONORRHŒA AND OTHER INFECTIONS. (a)

By J. PORTER PARKINSON, M.D.LOND., M.R.C.P., F.R.C.S. ENG.
Physician to the North-East Hospital for Children.

THE author opened his paper by recapitulating the striking results obtained by Dr. Fenwick and himself in gonococcal septicæmia, pyæmia, and arthritis, which were published in a paper read before the Royal Medico-Chirurgical Society in April, 1906. He then alluded to the protean character of the gonorrhœal joint affections, of which Osler mentions seven varieties, and pointed out in which of these the serum was specially efficacious.

(a) Abstract of paper read at the December meeting of the Therapeutical Society.

In the *arthralgic* type there are wandering pains about the joints, with neither redness nor swelling, sometimes lasting for years, and in this the serum may produce an unexpected improvement. A gentleman, about 60, who as a young man had suffered from gonorrhœa, followed by "rheumatism," had never been quite free from pain in the knee-joints, and during the last ten years it had become so severe that he was unable to go upstairs except on his hands and knees. There was no enlargement of the joints or ends of the bones, Five or six months ago he was treated by three rectal injections of polyvalent antistreptococcus serum on alternate days, after which the pain and stiffness gradually improved, and for the last few months he has been free from pain for the first time for years, while the stiffness also gradually lessened, and has now disappeared.

He related also notes of another case of ten years duration of the same type in which the serum was equally successful. *Chronic hydrarthrosis* of gonorrhœal origin is frequently monarticular, involving a knee-joint, and often associated with a prolonged gleet or a urethral stricture. The effect of the serum is not so satisfactory in these cases.

The *bursal and synovial form*, which attacks chiefly the sheaths of the tendons, may be combined with the more serious type in which endo- and peri-carditis, pleurisy and evidence of a general infection occur. In these the effect of the serum is remarkable, as shown in the former paper. Where the disease is limited to the sheaths of the tendons and bursæ, a rapid disappearance of the pain is to be expected, though some swelling may remain for weeks.

In the *polyarthritic variety* the serum seems always to effect a rapid and permanent improvement. Further experience of the treatment in cases of acute urethral gonorrhœa have shown that it is not very efficacious, though as the former paper showed, the gonococcus is inhibited from growing in a culture to which this serum has been added, though it will flourish in a similar culture in which the antigonococcus serum is present.

The author remarked that he had recently tried the effect of the serum in cases of fibromyositis, such as lumbago and so-called muscular rheumatism, with a good proportion of cases in which the treatment was successful, some of which he related, where one injection of 20 c.c. was followed by complete cessation of the symptoms. He considered there was now little doubt of the connection of these symptoms with certain microbic diseases, of which gonorrhœa is one. These organisms or their products produce a local reaction in certain fibrous structures, with inflammatory proliferation of tissue, and hence the racking pains.

At present it is impossible to say which organism is the causal factor, and so a rational serum treatment cannot be employed, but trial has shown that a considerable proportion of these cases yield rapidly to the serum injection in the absence of any other medication.

The writer did not wish to claim for this treatment more than its due, but considered the results already obtained are sufficiently encouraging to suggest a more extended trial of the remedy.

He finally alluded to the results obtained by Dr. S. Fenwick and himself in cases of purpura hæmorrhagica, which have been previously published.

NOTES FROM THE FRAUENKLINIKS OF HEIDELBERG AND FREIBURG. (*a*)

By H. MACNAUGHTON-JONES, M.D.

(*Continued from our last issue.*)

PART II.

HEIDELBERG.

I AM greatly indebted to Professor von Rosthorn, Dr. Kermauner and Professor Schottlander, as well as to the assistants in the clinic, for the most interesting work I saw while at Heidelberg. Professor Schottländer especially I have to thank for the time given to me in the pathological laboratory, and for the specimens which, through his kindness, I am enabled to show to-night.(*b*)

Asepsis is here carried out with the same scrupulous care insisted on in all German clinics. The method is: thorough ablution with Schlinck's mercuric soap without brushes, then alcohol-mercuric sterilisation; gloves are used. Gut is the principal material employed, the skin being closed with Michel's clamps. Trendelenburg's position is adopted in nearly all gynæcological operations, notwithstanding the spinal anæsthesia, though not to an extreme degree.

Every operation I saw was performed under the influence of spinal anæsthesia. The lumbar area is prepared by thorough scrubbing, and then painted over with iodine. The puncture is made between the first and second lumbar vertebræ; the spinal fluid, when aspirated, is mixed with the novocain and re-injected. Two injections have been previously given of 0.0003 scopolamin and 0.007 (gramme) morphia. The dose of the novocain, 0.1 to 0.15 gramme. An anæsthetist always sits at the head of the patient to give chloroform if required to supplement the spinal anæsthesia. This was occasionally necessary in very long operations, the quantity given being always carefully ascertained. It is generally but a very small amount.

I saw anæsthesia maintained in this manner in two Freund's operations, in which careful search was made by Dr. Kermauner for any infected glands, in ventro-suspension, plastic operations on the vagina, and adnexal operations. The severest and longest operation was a Freund, in which a large solid carcinomatous ovarian tumour, fixed by adhesions, had to be removed from the right side of the pelvis before the uterus was taken, and finally a solid metastasis, which grew from the wall of the bladder and involved its opening, was ablated. (Vaginal iodoform gauze drainage was used in the pan-hysterectomies.)

I need not remind you of the splendid work which has emanated from the Heidelberg Klinik, and to which Dr. Karl Kehren, who is not now on the staff, has so largely contributed.

Amongst recent investigations at this clinic is that of Professor Rosthorn, *Tuberculosis in Pregnancy.* In this paper the whole bearing of pregnancy on pulmonary tuberculosis is dealt with. He shows the aggravation of tuberculosis by pregnancy, and the unfavourable influence of parturition—this whether at abortion or at full period. He deprecates induction of labour, the only time that it can do good being in the early period. Later on, expectant treatment is best. In quiescent, stationary, and well-localised cases pregnancy has not such pernicious consequences. The

---

(*a*) Read at the British Gynæcological Society, on Dec. 13th, 1906.

(*b*) These included a unique complete section of a normal hypertrophied ovary; primary adeno-carcinoma of the ovary; lymph-endothelioma in a uterine polypus; carcinoma (primary) of the Fallopian tube; adeno-carcinoma of the uterus; &c. (Shown with the Epidiascope).

more serious the complication, the graver the effects of pregnancy. No set rule can be laid down for interference.

Another of Professor Rosthorn's later communications deals with his experiences in *Operating on Recurrent Uterine Cancer*. Seven operations were done by the abdominal method. The earliest case operated upon remained free from recurrence at the end of three years. Three cases are still living. One died, but this was inoperable, and only an exploratory incision was made. Owing to adhesions, difficulties of buried stitches, and deep pelvic hæmorrhage, &c., some of the operations took from two to three hours. When it was not possible to deal with the ureter it was simply ligatured, and in two cases when this was done no ill effect followed. The involved kidney atrophied.

Rosthorn's conclusions are :—(1) Even advanced cases of recurrent growth can be operated on by the abdominal route. (2) Scar recurrences preponderated over gland recurrence. (3) In scar recurrent cases the glands were found free. (4) Where the glands were involved the results were more disheartening from rapid recrudescence of the disease. (5) The important point as regards recurrences is the topographical relation of the growth and the involvement of other organs.

An interesting example of an unusual accident from a myoma is recorded by Professor Rosthorn, viz., death from intra-abdominal hæmorrhage brought about by tear of a large superficial vein. When the abdomen was opened, within twenty-four hours from the onset of the symptoms, it was found full of blood. The patient died forty hours after operation.

Rosthorn's *Operation for Cancer of the Cervix* is a very radical one. He removes the connective tissue and glands, clears the iliac vessels and the ureters, ties the uterine artery as far out as possible ; if the ureter cannot be implanted in the bladder it is tied, the peritoneal flaps are brought together, and the subperitoneal wound is packed with iodoform gauze, which is brought out into the vagina.

Last year Professor Rosthorn discussed the important question of the etiology and physical signs of *Adenomyoma of the Uterus*. He notices the connection between tuberculosis in children and delayed puberty, with amenorrhœa and sterility in after life, as associated with adenomyoma. There are attacks of pelvic peritonitis, and urinary affections are common ; short vaginal canal, anteflexion of the uterus (which may be infantile) and conical cervix ; at times there is a flattened protuberance on the posterior wall of the uterus, and a tendency of the growth to invade the cervix.

The most important of the recent researches of Dr. Kermauner is that on *The Anatomy of Tubal Pregnancy*. This is a careful investigation of the tubal changes, the presence of a pseudo-decidua reflexa, and the formation of hæmatocele. Five cases proved that fœtal elements can penetrate the maternal tissue, and these can be traced to the lumen of the maternal vessels. Only in six out of forty cases were decidual changes found in the tubal mucosa.

Pubiotomy.—Professor Rosthorn has had one death. It occurred from uncontrollable venous hæmorrhage. No artery was injured.

Freund's Operation.—Rosthorn considers that Freund's name should be the one associated with the radical operation for cancer. Freund first removed the glands, and was followed in the attack on the parametrium by Emil Ries and Rumpf.(*a*) He considers that the question of the future is that of the removal of the glands. He does not practise Schuchardt's operation. If the malignant disease be localised, then the old vaginal panhysterectomy is sufficient ; if the connective tissue be involved, then the abdominal route is best.

Puerperal Infection.—Professor Rosthorn believes in Trendelenburg's suggestion of attacking the thrombosed pelvic veins by ligature or extirpation. Death had followed in one case, but here there was pus in the pelvis.

FREIBURG.

I do not intend to delay to describe the details of the Freiburg Klinik. Enough for me if I arouse sufficient interest in your minds to induce you to visit it and see the installation for yourselves.

A prominent feature is the powerful electric light, which is so arranged at the end of the theatre opposite the window (the latter being constructed like a half horseshoe, running from the ground to half-way along the ceiling) that it can be directed on a mirror placed at such an angle as to reflect the light directly into the pelvis, thus avoiding the unpleasant heat which is experienced from the electric lamp reflector. I was struck also by the small nickel-covered openings through the tiled walls for the passage of any sterilisation appliances, or the sterilised saline solution direct from the steriliser. And yet, with all this apparent perfection, I learn from Professor Krönig that the State is about to build a new theatre, a short distance from the present one, and still more perfect. Truly, the State recognition of excellent work in Germany is an object-lesson to the world !

Anæsthesia.—All the cases I saw operated upon, either by Professor Krönig or Dr. Penkert, in the Frauenklinik were treated by medullary anæsthesia. These included abdominal, vaginal, and perineal operations. For example, there was a complete procidentia uteri, with prolapse of the bowel, and a laceration of the rectum, without exception the worst case of its kind I ever saw. Professor Krönig completed this operation without any sensitiveness on the part of the woman, in about half an hour. In this case the tissues were also subcutaneously injected with novocain. In no single instance did I see the least evidence of sensibility in such operations as hysterectomy, removal of the adnexa and appendix, and plastic operations on the tubes. The drugs used were scopolamin-morphine, and stovain " Billon."

Two hours before operation, the scopolamin 0.003 with morphine 0.01, in aqueous solution, is given, and the same dose is repeated one hour before operating. Immediately before operation, the stovain " Billon " is introduced into the spinal canal, taking about two minutes for the injection, which prevents quick distribution along the cord to the medulla. Rapid injection is injurious through the pressure it causes. After the introduction of the stovain, the patient sits up for two minutes. The process is the same as in making ordinary lumbar puncture, and the point usually selected is between the second and third lumbar vertebræ. Following the injection, and all through the operation, a strong light or any noise is avoided, and to accomplish this, Professor Krönig places large dark glasses over the patient's eyes, and large pads of gauze over the ears. Sharp or piercing noises are sure to disturb the patient.

This method of anæsthesia is used in all abdominal, vaginal, perineal and obstetrical work, but according to the nature of the operation different dosage is used. In vaginal, perineal and obstetrical work, including forceps, version, &c., the usual dose of scopolamin-morphine is given, but of stovain " Billon " only 0.06, while in abdominal work a larger dosage is practical, the stovain " Billon " being increased to 0.12. The only contra-indication observed by Professor Krönig is extreme old age, and even then this form of narcosis is not altogether contra-indicated, but smaller doses are used. This method Professor Krönig regards as satisfactory for gynæcological purposes.

Post-anæsthesia is unaccompanied by any disagreeable symptoms whatever—even headache is frequently absent. Several cases have been operated upon successfully with severe mitral and other valvular lesions.

Billon (Paris) uses smaller doses than Krönig, with immedate Trendelenburg posture, with the idea of spreading it. The period of complete anæsthesia under its influence is from one to one and a half or two hours ; following this period sensation begins to reappear.

Out of a series of 380 gynæcological, and 130

(*a*) Emil Ries first removed the pelvic glands in 1895.

obstetrical operations carried out to date at the klinik, Professor Krönig records but two deaths following this form of anæsthesia.

Case I.—Patient, æt. 64, with carcinoma of uterus. Died two hours after operation.

Case II.—Case of uterine myoma with aggravated mitral lesion. Had been previously refused for operation by other surgeons. Death occurred before the operation could take place.

In these cases the usual scopolamin-morphine dosage was given, followed by stovain 0.009, and Professor Krönig thinks that the dosage may have been too great for such cases. He now uses a smaller dosage, and has never seen either respiratory or cardiac disturbances or depression.

Altogether, he looks on this form of anæsthesia most favourably.

Professor Krönig has devised an apparatus which rolls on castors, and which contains in separate compartments chloroform, ether and oxygen. By moving an indicator the desired vapour is turned on to the mouthpiece, and the quantity is regulated. Two of these charged anæsthetisers are always at hand in the theatre.

Sterilisation of the Hands.—This is completed, after ten minutes' scrubbing, by washing for five minutes with sublamin, 1 in 1,000 (Scherin, Berlin). When the hands are dried, they are coated over with a covering of zylol paraffin, 5 per cent. Rubber gloves are not used in ordinary cases—only in carrying out spinal anæsthesia and where there are septic conditions, or when the rectum has to be explored.

Trendelenburg's Position.—I noticed that this was seldom resorted to, and, in consequence of the cardiac complications in some myomata, Professor Krönig considers it contra-indicated in operations in these tumours. Also, in spinal anæsthesia he believes it favours the too rapid distribution of the anæsthetic along the cord to the medulla. The objection is based on his experiments on dogs. Out of a series of eight dogs, in which the stovain was tried, out of the first four, on which immediate Trendelenburg position was tried, three died. In the case of the remaining four, in which the Trendelenburg position was not tried, nothing untoward happened.

Material for Sutures and Ligatures.—Catgut is almost entirely used save in enterostomy and appendisectomy, and as re-inforcing sutures (three in number) of the wound in Cæsarian section.

Professor Krönig nearly always adopts the *Pfannensteil Transverse Method* of opening the abdomen, believing that the closure of the wound after this method affords greater strength to the abdominal walls and support to the viscera. This incision is specially used in operations on myomata, and in morcellement, and always in Cæsarian section. He reserves the longitudinal incision for certain carcinomatous cases, but now uses it very rarely.

When the fascia is divided it is caught up above and below the incision, and is attached to the skin by a single suture, which saves the necessity for a retractor and keeps the wound well open. An assistant uses lateral retractors to draw apart the recti muscles and peritoneum. At Freiburg, as at Heidelberg, the second stands (on a small platform if the Trendelenburg position be chosen) between the thighs of the patient.

Cystoscopy.—The principal methods followed are Luy's and Nitze's, with a preference for the former; Kelly's seldom.

Skiography.—In skiographing the ureters and pelvis of kidney, the ducts and pelvis are filled with xeroform oil. This defines the urinary tract. I saw a most interesting series of skiographs illustrative of the various abnormal conditions of kidney and ureters, taken by Professor Krönig in this manner. A few notes on certain gynæcological and obstetrical questions may be of interest.

Removal of the Appendix.—This is practised as the rule in all abdominal operations, whether the appendix be normal or otherwise, unless the additional length of time involved be detrimental in a prolonged and exhaustive operation. Curiously enough, I saw at the klinik one case, operated upon by Professor Krönig, in which the appendix was absent.

Wertheim's and Schuchardt's Operations.—In general, Wertheim's method is followed, save in very obese women, when Schuchardt's is preferred. If abnormal, the glands are removed. The Wertheim method is carried out in 90 per cent. of the cases.

Suspension of the Uterus.—Save in cases where there are adhesions and adnexal complications (when ventro-suspension is practised) the Alexander-Adams operation is performed.

Lavage of the Abdomen.—This is rarely employed.

Pubiotomies.—Professor Krönig has performed thirty of these, without any maternal death; two children died. When the head is high, there is the danger of rupture of the bladder. This danger is minimised if the bladder be low. He does not consider pubiotomy in any sense superior to symphisiotomy.

Postpartum Management.—The patient, after normal labour, rises the day following delivery, and is taught deep-breathing exercises up to the sixth day, after which she pursues such gymnastic exercises as arching of the spine while lying on her back, and elevation of the lower limbs. Alternate douches of hot and cold water are given over the perineum, thighs, and abdomen, to stimulate muscle tone. Postpartum peritonitis is usually treated by multiple abdominal openings to allow of free drainage. Professor Krönig in some cases unites the cæcum to the abdominal wall until the symptoms subside, subsequently closing the fistula. He has not yet operated for septic thrombosis or cellulitis by the methods advocated by Trendelenburg—viz., removal of the thrombosed veins.

In *Antepartum Eclampsia* rapid removal of the child is the main indication. For this purpose the cervix is divided, and the delivery completed by Duhrsen's method.

Gentlemen, my excuse for detaining you at such length is that it must happen to all of us that we are occasionally tired of hearing our own voices; perchance —more rarely—that we are wearied of the perpetual chanting of our own deeds, and the doxologies which wind up the recitals of our victories—often not very glorious ones—over our common enemy, disease. Even our failures afford us a certain grim satisfaction, and it might be well for us if they taught ourselves and our hearers even more than our successes.

It is a break, then, in this monotonous rhythmic monthly recital of what the "I" is doing, to change to the possibly more instructive description of what "they" are doing. We get down from the giddy heights of our self-satisfying survey of our excellencies to the lower plain of the more humble if not humiliating realisation of what some masters in our art can teach us.

CLINICAL RECORDS.

A CASE OF ACUTE HÆMORRHAGIC PANCREATITIS.

(*Fatal termination within three-quarters of an hour from onset of symptoms.*)

Under the care of F. W. BAKER YOUNG, M.B., Ch.B. (Vict.),
Clinical Assistant, Hospital for Women, Liverpool.

PATIENT was a male, æt. 30, a fitter by trade. On December 28th, 1905, he was taken ill while at work. Remarking to the foreman that he was out of sorts, he walked home, and almost immediately expired. On my arrival the patient was dead. He was lying in bed on his back. His expression was tranquil, skin pale, pupils dilated.

The past history was as follows:—A native of Ireland, he had come over to England about five years ago, and, as far as known, he had never had a day's illness. He was in the habit of excessive beer-drinking, the bouts often lasting several days. This Christmas he had taken his share of beer, but was not thought to have been intoxicated. On the day of his death he resumed work for the first time after Christmas. He refused breakfast before starting at 9 a.m., and should have worked until 1 p.m.; but at 11.45 he told the foreman he was ill and would have to knock off, but made no further complaint. He went home, a distance of fifty yards, and some bovril was prepared; but after waiting for it he refused to touch it, and said he would go upstairs and lie down. Ten minutes later he was heard to be choking, and on his friends going up to him he was unable to speak, although he recognised them.

Autopsy (twenty-eight hours after death).—No marks of violence to be seen. Rigor mortis well established. Post-mortem stains present only over dependent parts. Surface quite cold. No discharge from external orifices. The body was particularly well nourished. On opening with usual incision, marked engorgement of the omental veins was observed. No fluid in pleuræ. No adhesions. Pericardium contained 1 oz. of pale, straw-coloured serum. Heart and lungs removed, floated *en masse*.

Examination of Heart.—Right side contained very dark fluid blood, but was not distended. Left side quite empty; valves and coronary vessels healthy. Septum ovale complete. Aorta healthy. Œsophagus healthy. Trachea of a reddish colour; contained a large quantity of frothy mucus. Larynx healthy; no obstruction.

Lungs.—Upper lobes normal, with exception of a spot one inch below apex on the anterior surface of right lung, where a healed phthisical lesion was found, containing a calcareous nodule the size of a Barcelona nut. The lower lobes in their entirety were engorged with dark fluid blood. On section, air, frothy mucus, and blood could be freely expressed. Portions floated in water.

Peritoneum.—Old firm adhesions found around appendix and cæcum. On introducing the hand into the lesser sac it came out stained with blood, and on opening the sac about two ounces of blood-stained fluid were found, and the position of the pancreas appeared to be occupied by a large blood-clot. The stomach was now ligatured and removed. Liver also removed, and on manipulating the intestines the pancreas was exposed in its whole length. It was now obvious that there had been a large hæmorrhage involving the body and tail of the organ, the head in comparison being free. The organ was dissected out, and was of a dark-red to violet colour, and on longitudinal section was found to be infiltrated with fluid blood. It weighed 6¼ ounces.

Stomach contained less than one ounce of bile-stained mucus. Post-mortem changes on posterior wall; otherwise healthy.

Liver.—Enlarged, somewhat fatty, engorged with venous blood. No gall-stones. Biliary ducts patent.

Spleen.—Normal in size, but on section darker than usual; rather friable and engorged with venous blood.

Kidneys slightly enlarged. In the left kidney there was an ecchymosis on its anterior surface, about 1½ inches in length and three-quarters of an inch broad, with its long axis parallel to the long axis of the kidney, and situated over the lower segment of the upper half or the organ. The capsule stripped with difficulty, but could not be removed from over the ecchymosis. On section through this portion the hæmorrhage did not appear to penetrate the kidney substance. *Right Kidney*.—Capsule stripped, but not so readily as usual. Other abdominal viscera normal.

Brain and Meninges.—The meningeal and cerebral veins and sinuses were engorged with dark fluid blood; brain and upper portion of the cord otherwise healthy.

Microscopic Section of Pancreas.—Dr. H. Clarke kindly cut sections of the organ for me, but, owing to the fact that I was unable to give him the specimen until forty-eight hours after death, it is impossible to give a certain opinion on the condition. The section showed necrotic areas, with a certain amount of hæmorrhage; but so much auto-digestion had occurred that it was impossible to state whether the necrotic patches were ante- or post-mortem.

The literature on the condition is not extensive. Von Ziemssen divides hæmorrhagic pancreatitis into three classes:—

1. Large hæmorrhagic masses due to pre-existing changes in vascular system. 2. Hæmorrhages into pre-existing retention cysts. 3. Cases in which the entire organ takes on a hæmorrhagic condition, death in these cases often occurring very suddenly. In these cases, besides the hæmorrhagic infiltration, fatty necrosis of the organ is found. Moynihan states that, in cases of hæmorrhagic pancreatitis, hæmorrhage may precede or follow the inflammatory stages. In those cases in which the hæmorrhage appears first, a fatal termination may take place before the inflammatory changes have had time to make their appearance.

The following points were of interest in my case:—

1. Age. The disease has generally occurred after the fortieth year.

2. Rapid onset and equally rapid fatal termination. Most authorities, including Allbutt, Osler, and Butler, give as the fatal period from two to four days, with occasionally the saving remark of "sometimes earlier."

3. Absence of vomiting may in this case be accounted for by the patient not having taken any food since the previous night, although he was noticed to be retching when he ceased work.

4. Absence of pain severe enough to make patient complain. He was only observed to hold his hand to the pit of his stomach.

5. Situation of hæmorrhage—the usual site being in the head and neck. Here the principal effusion occupied the body and tail, which point, perhaps, would account for the rapid termination, owing to the effect the lesion would have on the solar and semilunar ganglia.

6. The well-marked venous congestion and fluid state of the blood. These last two conditions I am unable to account for, and so far have been unable to trace any similar condition found in published cases.

OPERATING THEATRES.

GREAT NORTHERN HOSPITAL.

Operation for Strangulated Femoral Hernia.—**Mr. Arthur Edmunds** operated on a woman, æt. 50, who had presented herself at the out-patient department with a small lump over the saphenous opening. This lump had been present for two or three weeks, but had not given rise to any considerable discomfort; ultimately, however, she consulted her doctor, who sent her on to the hospital. The swelling was about the size of a small walnut, and situated below Poupart's ligament and internal to the vessels. Its nature was not very certain, but in view of its position, and of the fact that there seemed to be a pedicle passing from the deep surface of the tumour, the diagnosis of femoral hernia was made. There was, however, no impulse on coughing, and taxis, which was painless, had no effect on the swelling. Admission to the hospital was advised, but the case was not deemed urgent, there being no symptoms suggesting possible strangulation. While she was waiting for her name to be entered on the list of patients for admission, she vomited, and Mr. Edmunds decided to admit her for immediate operation. Accordingly, the patient was anæsthetised, and a curved incision with the concavity inwards was made round the swelling; the skin and fat were then raised in a flap, and the hernia exposed. This flap incision has the advantage, Mr. Edmunds said, that the resulting wound is situated further from the perinæum than that resulting from a straight incision, and further, the skin sutures are not directly above the deeper ones, so that any soiling of the wound subsequently to the operation is less likely to cause deep infection. The sac was now cleaned, and a quantity of retroperitoneal fat removed. The sac was found to be distended with fluid, and when this was let out a small knuckle of bowel was seen projecting through the femoral canal. The neck of the hernia was incised inwards in the usual way, and the bowel pulled out for examination. It was then seen that the whole of the circumference of the gut was not involved, the hernia being of the type known as Richter's hernia. There was no question about resection; the bowel would obviously recover, although considerably discoloured, and accordingly it was returned to the abdomen. The sac was transfixed, ligatured and cut away. The question now arose of the closure of the femoral canal. The radical cure of femoral hernia presented, Mr. Edmunds remarked, many difficulties which do not obtain with the inguinal variety. Operations designed for this purpose, he said, fell under three headings: (1) in the first an attempt is made to suture Poupart's ligament to the deep crural arch, and to the periosteum of the pubes. This would be quite a satisfactory operation were it not for the fact that these fibres are too feeble to hold the sutures satisfactorily. (2) In the second group of operations a flap of pectineus is turned up and drawn into the femoral canal by means of a mattress suture Unfortunately this proceeding deprives the reflected portion of the muscle of its innervation; as a result of this, the muscle atrophies and the operation fails. (3) The third type of operation was, he considered, the only one which could claim the title of a radical operation, and in this an attempt is made to fix Poupart's ligament definitely to the bone itself. Two methods are employed in Raux's operation. A staple, similar to that used to fix up electric bell wires, is passed through Poupart's ligament, and then hammered well home into the pubes. This, Mr. Edmunds thought, was a good operation, but the staple had a tendency to work loose, especially if it had not been hammered tightly home, and, in any case, the pressure of the staple will cause absorption of the bone around it, so that it cannot hold for any great length of time. The method adopted in the present case was that described by Nicoll ("Annals of Surgery," January, 1906). After the sac had been ligatured and pushed back into the opening, the anterior surface of the pectineus was exposed and an incision made along the middle third of its pelvic attachment exposing the pubes. A copper spatula was then introduced below Poupart's ligament behind the deep surface of the pubes, and two holes, about three-quarters of an inch apart, were drilled through the bone. A curved needle bearing a strong strand of silkworm gut was now passed deeply through Poupart's ligament, and the muscular structures attached to it. A piece of silver wire about a foot long was next taken and bent in half, so as to form a loop. This loop was passed through one of the drill holes and hooked up into the wound. One end of the silkworm gut suture was then put through the loop, and the loop withdrawn, carrying one end of the silkworm gut with it. The manœuvre was repeated with the other drill hole, so that the two ends of the silkworm gut suture which had been passed through Poupart's ligament and the abdominal muscles were drawn through the pubes from the deep to its superficial aspect. The suture was now tightened and tied, thus drawing down the structures which formed the anterior wall of the femoral canal to the postero-superior aspect of the pubes, and thus obliterating the canal. A few points of catgut suture were then inserted to attach the fascia over the pectineus to the external oblique. The wound was then closed. Mr. Edmunds said that at first sight this operation seemed complicated, but it was in reality very simple. The actual passage of the suture with the aid of the wire loop need not take more than from five to seven minutes, so that the operation is feasible even for cases of strangulated hernia. The result was extremely satisfactory, and the patient need wear no truss. He pointed out also that the operation he had just performed differed from the one described by Nicoll in one or two minor points, mainly in the employment of the wire loop in place of a probe and a loop of catgut.

TRANSACTIONS OF SOCIETIES.

THE SOCIETY FOR THE STUDY OF DISEASE IN CHILDREN.

Special meeting held on Friday, December, 14th, 1906.

Dr. E. Cautley in the Chair.

The subject for discussion was

Rickets,

which was taken under the following five headings.

The ætiological aspect was opened by Dr. **Dudgeon**, who discussed the climatology and the question of heredity.

The lactic acid theory of Heitzmann, and the lime theory of Voit were discussed and shown to be untenable. Mr. Bland Sutton's well-known experiments on the lions at the Zoo were detailed, and also the recent work of Dr. Chalmers Watson on rats, whose mothers had before pregnacy been fed on a meat diet and the young animals also fed on the same; changes were found in the bones resembling rickets, but the microscopical changes were different. He also mentioned that in all cases of status lymphaticus changes occurred in the bones resembling those of rickets. He considered that there was no evidence as yet in favour of a toxic theory.

The symptoms and diagnosis were discussed by Dr. **Poynton**, who remarked that rickets was a disease beginning insidiously during the first two years of life. Early warnings were anæmia, general flabbiness, and profuse sweating about the head. The osseous symptoms were often the first to attract attention, but much tenderness of the bones points to scurvy or osteogenesis imperfecta. Fractures are less common than usually supposed. Head-nodding is due to a local irritation from the teeth or ears. Craniotabes is much commoner in syphilitic rickets. Hirschgarser found rickets in 89 per cent. of cases of laryngismus stridulus and in 79 per cent. of tetany. A convulsion in a rickety child might be the beginning of epilepsy. He believed in the existence of fœtal rickets, but suggested a discussion as to the nature of late rickets. Was it a true rickets? and, if so, was it a relapse of early rickets or did it develop *de novo*? Under diagnosis he alluded to latent syphilitic rickets, achondroplasia and osteogenesis imperfecta, the latter disease being characterised by its congenital origin, the frequency of fractures, softness of bones, and by failure of anti-syphilitic and anti-rachitic remedies.

The discussion on pathology and morbid anatomy was opened by Dr. **Milligan**, who, after discussing the various experiments performed on animals with a view to ascertain what the essential pathology of rickets was, pointed out that no definite result had as yet been arrived at. The morbid anatomy was illustrated by many gross and microscopical specimens. The visceral changes in the liver, spleen and lymphatic glands were described, and it was commented on that it was curious that no changes had been found in the central nervous system considering the frequency of nervous symptoms.

The discussion on the surgical aspect was opened by Mr. **Betham Robinson**, who, in drawing attention to the common deformities, made a special reference to genu valgum, and considered it offered points for discussion. The use of skiagraphy had thrown much light on the pathological conditions present.

swallowing might also be an early symptom of struma. The disturbances of circulation and of the heart, such as arhythmia of the pulse and omissions, &c., were not the direct results of compression, but were to be explained by pressure on the laryngeal nerve. Disturbances of the local apparatus were extremely rare, so long as the struma was not malignant. The anatomical structure of the struma gave no key to the kind of trouble arising from the disease. Simple parenchymatous hyperplasia was more common in youth; the colloid or cystic degeneration follicle in later life. Vascularity varied enormously.

The external use of iodine the speaker considered of no value, but it had an undoubted influence sometimes when given internally, and particularly so in young people. The same might be said of thyroidine and similar preparations.

Injections also of iodine or iodoform were not always without effect, but the speaker had given them up on account of the danger attending them, and because, if operation had still to be performed, it was made much more difficult by the previous injection.

He therefore, when the patient was young, first of all gave iodine if the case was one of simple hyperplasia; if this did not succeed after trial, he proceeded to operation. In older patients he proposed operation at once.

The question was: Extirpation or enucleation? The latter only, however, came into question in encapsuled goitres. But even then enucleation was not advisable. Generally besides the encapsuled cysts there were others that were not visible at first, and which led to recurrences; moreover, the hæmorrhage might be very great in such enucleations. Taken as a whole, enucleation was only advisable in superficial easily accessible, isolated cysts, which could be recognised as such through the integument.

Otherwise, extirpation was advisable under all circumstances. This, thanks to Brons, Kocher and others, had developed into a typical operation that, rightly performed, entailed but little loss of blood. The vascular condition, it was true, was very variable, but if one proceeded systematically, and keeping the varieties in view, any free hæmorrhage, might be avoided.

For the skin, the speaker preferred the horizontal "cravat" incision, which for cosmetic reasons, should not be longer than circumstances required. It was important to take care of the laryngeal nerve that it was not included in the ligature of the inferior thyroid artery. If possible, a general anæsthetic should be avoided, and in place of it two or three injections of a 1 per cent. solution of cocaine might be given. Patients felt no actual pain during the operation, but only the disagreeables such as difficulty of breathing, which, however, ceased as soon as traction on the goïtre ceased. As compensation, they did not vomit after the operation.

After operation patients often had transient troubles both with breathing and swallowing; any bronchitis present often got worse or pneumonia developed. Post-operative temperature also varied very much, but suppuration never followed.

The mortality did not amount to more than 0.3 to 0.5 per cent. When death took place it was from pneumonia, secondary hæmorrhage, or cardiac failure in patients with already irregular hearts.

The prognosis was therefore good, and he advised operation whenever the goitre was the source of trouble.

It was very different, however, with malignant goitre. These were generally rapidly growing hard tumours, or an ordinary soft goitre become hard. They occurred in comparatively young people of thirty or but little over. They looked well, and yet these malignant goitres soon became inoperable, as tumour thrombi formed early in the vessels. Of twenty cases of malignant goitre that he had operated on only one remained free from recurrence for a year. All the others died either from the operation or from rapid recurrence. As benign goitres might undergo malignant degeneration, and as the prognosis in this class of cases was so extraordinarily bad, this was another cogent reason for early operation.

Hr. Levy-Dorn remarked on the absence of permanent results in cases treated by X-rays.

Hr. v. Hausemann spoke on discrimination in using thyroidin. In parenchymatous hyperplasia it was useless, but sometimes did good in colloid or cystic degeneration; the follicles might become smaller, but not fewer in number.

Hr. Mendel mentioned a case that showed caution should be exercised in using iodine in the treatment of goitre. The goitre disappeared, but Basedow's disease developed, which, however, improved under thyroidine.

Hr. Unger had never seen a cure from X-rays, although he had used it in about 30 cases.

AUSTRIA.

Vienna, Dec. 30th. 1906.

ATHEROMATOSIS OF AORTA AND SYPHILIS.

Ehrmann presented a patient to the members of the Gesellschaft suffering from an atheromatous condition of the aorta associated with a gyratory form of tubercula cutanea syphilitica. An interesting feature in this case was a white marble shadow of a tree on the skin over the pelvic region, which was also strewn with tubercles of a syphilitic nature. These neoplasms were distributed over the cutaneous surface of the trunk and limbs.

Ehrmann thought this phenomenon was very rare, or little understood, although four such cases had recently come under his own personal observation; all of them with the atheromatous aorta and enlarged vessels.

The microscopic examination informs us that a sclerosis of the arterioles exists and is probably the cause of the phenomenon. Owing to this sclerosis the wall of the vessel becomes rigid, so that cardiac systole of the left ventricle is lost after entering these inelastic tubes, which become mere sinuses for the reception of the blood, as they have no power to propel it through the capillaries. If the vessels lying in diastole be rubbed in the direction of the current the blood can be forced through the capillaries mechanically, but no contractions in the vessels will be produced, as the stiff arterioles will again resume their rigid state, becoming congested with the next systole.

With this form of arterio-sclerosis we have produced a cutis marmorata or an extensive maculose exanthema. In the early eruptive stage of syphilis we have an efflorescence appearing as a livid copper-coloured syphilide. If one of these efflorescent patches be excised, the spirochetæ pallidæ of Schaudin will be found in the walls of the vessels and neighbouring tissues. Now it is assumed that these microbes persist, as this often recurs, and thus increase the sclerosis in the vessels which would soon produce the cutis marmorata, as that seen in the case presented.

PITYRIASIS LICHENOIDES CHRONICA PRURIENS.

Ehrmann also showed a girl, æt. 13, with small glittering nodules resembling lichen ruber. The more advanced desquamated like psoriasis, a white covering leaving a dark orange-coloured surface. The treatment usually followed in psoriasis was adopted with very transitory results, owing, no doubt, to our ignorance of the etiology.

PERFORATION OF STOMACH HEALED.

Schnitzler exhibited two cases where he had performed laparotomy for perforation of the stomach, with excellent results.

One of the cases was specially interesting from the fact of its having been done twice for the same thing, which Schnitzler considers positive proof of the practicability of the operation. The origin of these ulcers was due to a preceding operation of gastro-enterostomy, which invariably produces ulcers in that organ after the healing, and function of the stomach has commenced. Both of these perforating ulcers commenced within a year after the gastro-enterostomy. He is of opinion that stenosis calls for early operation; but where there is no mechanical obstruction and the ulceration has proved deficient to all internal treatment, the surgeon should not hesitate to operate.

Eiselsberg said that he had long ago recognised the treatment of ulcers of the stomach by surgical means as the best and most effectual. He would go further and recommend jejunostomy where the patient was very weak and unable to absorb enough of nutrition to keep the body up.

"Huhnerpest."

Schiffmann showed a number of microscopic preparations taken from the blood of fowls suffering form the pest.

Paltauf said these demonstrations opened up a wider field for speculating on the convection of disease, as the product of cell degeneration seemed to be an active agent in disseminating disease. To this group he would assign Guarnieri's small bodies which we meet with in variola and vaccine. Two days after a fowl has been very ill with the pest no micro-organisms can be found in the blood, tissue, or organs of the animal, although the disease is intensely infectious at this stage of the illness. If the disease last for one or two weeks, *i.e.*, the animal survive one week, the virus will be found to localise itself in the brain, where relatively large cells will be found encysted or in a state of quiescence with all the properties of the virus. There are no micro-organisms to be found—nothing but these enveloped bodies which are evidently the product of cells, and contain all the virus of the disease in an invisible form of division.

Rontgen Rays and Metabolism.

Reuss gave a report of his experiments with the Röntgen rays on the healthy subject. The rays, when intense, do not greatly increase the elimination of the nitrogenous bodies, but this slight increase continues for a few days after the application, and again falls back to its normal condition. The elimination of P_2O_5 commences rapidly and ceases speedily after the rays are withdrawn, but the constituent P_2O_5 is slow in recovering and appears in very small quantities in the secretions for a long time after the exposure.

This is parallel with the changes observed in the blood where a sudden form of hyperleucocytosis appears from some explosive change in the lymphoid tissue continuing for twenty-four or thirty-six hours. During this anatomical change the cholin appears suddenly in the blood and as quickly disappears, after which the PO_5 gradually increases. All this tends to prove that lecithin and its allies are the substances principally attacked by the Röntgen rays.

Cholesterin and Gall Bladder.

The controversy of cholesterin being formed in the gall bladder or secreted from the blood is far from being settled. Aschoff affirms from his results that cholesterin is extracted or separated from the gall after it has been collected in the gall bladder, and not obtained from the epithelial lining of that viscus, as affirmed by other physiologists. The substance is first secreted as a cholesterin ester with a neutral fat in combination. In the bladder this mixture is split up, the cholesterin remaining in the bile, while the neutral fat passes off in the lymphatics.

HUNGARY.

Budapest, Dec. 30th, 1906.

Dr. Kohrman Muller, Commissioner of Health of Budapest, stated the sources of typhoid fever in about the order of their importance as follows:—(1) milk, (2) fish, (3) uncooked vegetables, (4) imported fruits, (5) secondary cases, (6) ice, (7) domestic water supplies, (8) public water supplies. (Dr. Müller does not agree with Leverle, of New York, who counts flies also to the sources of typhoid). With regard to the milk supply, Budapest is ahead of any other city in caring for this, and while there is no doubt that many cases occur from milk infection, the danger is ever growing less. The uncooked vegetables are lettuce, tomatoes, and the like, which can only be imperfectly cleaned before being put on the table. At times typhoid fever has been traced to the use of night-soil for the manuring of these. As for ice, it has been shown that the mere freezing of water did not kill the typhoid germs in it. As a result of this investigation, a number of other investigations have been made, and now it is known that though the bacilli are not killed by freezing, they gradually lose their vitality when kept in a frozen state for any considerable period.

Dr. Hultl Humer read a paper in the Medical Society with the title, "For how Long a Time should we enjoin Rest in Bed after Abdominal Section?" Therein he stated that he allowed his patients up just as soon after operation as they chose. This statement aroused a great discussion. Many surgeons thought that any endeavour to diverge from the habitual in operative treatment should be welcomed, yet the safety of the patient should be the first consideration. The following factors have to be considered:—Condition of patient, character of operation, length and locality of incision, method of suturing and suture materials. In conclusion, it was accepted that the tendency to shorten the period of rest in bed is advisable, except for suitable cases, and that any attempt to shorten this period to a few days was a hazardous experiment.

The annual report of the Statistical Bureau shows an alarming increase of insanity among the Slav inhabitants of Hungary. The figures show unmistakable evidence of increase in insanity and mental degeneracy in the Slav race. It would take too long a chapter to attempt to explain all the causes to which the increase of insanity in the Slav population may be due. The patients do not seem to owe their mental downfall to excessive brain work, but rather to physical conditions and degeneracy to which their lax, indolent, inhygienic methods of living naturally lead. Hereditary influences, too, are gradually asserting themselves as a not insignificant factor in producing additional physical and mental defects in the race. Poverty and painful struggling for life may also have a considerable rôle in provoking so many insanity cases. The number of patients accommodated in hospitals during this year was 117 more than the previous year, showing an increase of about 50 per cent.

FROM OUR SPECIAL CORRESPONDENTS AT HOME.

SCOTLAND.

COMPULSORY NOTIFICATION OF CONSUMPTION IN EDINBURGH.

At a meeting of the Town Council, held on December 18th, a motion in favour of the compulsory notification of phthisis was carried by a large majority. The proposal was brought forward by Councillor Cullen, the convener of the Public Health Committee, whose statement on the subject we referred to a few weeks ago. Some of the objectors to the proposed inclusion of phthisis among the diseases scheduled under the Infectious Diseases Act took up the position that some of the clauses in that Act would bear hardly on consumptive patients, and urged that instead of proceeding as is proposed (namely, by approaching the Local Government Board for permission to schedule phthisis), the Council ought to obtain a provisional order enabling them to deal with the disease. Such objections have not been limited to the Council, but have been raised in letters to the *Scotsman*. Dr. Cullen, however, was able at the meeting of the Council to give such assurances in respect to the practical working of the Act as ought to relieve any anxiety which may exist that it will in any way operate harshly or oppressively on members of the community afflicted with consumption.

DR. MATTHEW HAY, ABERDEEN, ON THE MILK QUESTION.

A considerable part of the annual report on the health of Aberdeen is devoted to the important matter of a proper milk supply. Experience shows, he says, that with proper care and cleanliness in the production, transmission, and sale of milk, milk can be produced on a commercial basis, of such a quality that there is little need for sterilisation. One important step would be the replacement of registration of dairies by licensing which implies power on the part of the licensing authority to refuse, unless the required conditions are complied with. At present, every dairy, however unsuitable, can claim to be registered. Until Parliament grants such powers, Dr. Hay advises that the Town Council should institute a voluntary register of dairymen who agree to certain reasonable requirements, and would allow their farms to be inspected by veterinary inspectors. Such dairymen would have their names on a public list, and the consumer could be reasonably certain that he was getting wholesome, clean milk. Dr. Hay alludes to a recent English trial in which a dairyman was mulcted of several hundred pounds damages for allowing his milk to be infected with typhoid, and thinks that the trade ought to welcome any supervision which would reduce such serious financial risks. During the year the Public Health Committee conferred with the dairymen of the town as to the possibility of veterinary inspection of the dairies. The majority of the dairymen reserved their opinion, and were desirous of learning to what extent tubercle occurred in the milk supplies of the city. Dr. Hay accordingly made some investigations on 27 samples of commercial milk from various sources by inoculating guinea-pigs with 1 c.c. of centrifugalised milk. Two of the animals succumbed to tuberculosis; in one the disease was thought to be due to natural causes; in the other it was undoubtedly due to milk infection. There is thus no doubt that some of the Aberdeen milk is contaminated with tubercle, though the percentage is much less than in some of the English Midland towns. Since the conference took place certain of the leading dairymen have themselves arranged for veterinary inspection. What is required is that such inspection should be made general, and should be carried out by an official appointed by the Corporation as representing the consumers.

Epilepsy as a Defence in a Murder Trial.—A case of some medico-legal interest was tried before the Lord Justice Clerk in the High Court of Justiciary on December 17th. The prisoner was indicted for the murder of his wife by shooting her, and the line of defence was that he was of unsound mind. Dr. Clouston was the principal witness, his evidence being to the effect that the prisoner, having once been struck by lightning and subject to fits, would, if he took drink, be liable both to suicidal and homicidal impulses. In the intervals between the attacks he would be perfectly sane. There was no more dangerous class of men than those who were epileptic and sometimes alcoholic. In his charge to the jury the Judge laid considerable stress on the plea of mental unsoundness as entitling to an acquittal of the more serious crime of murder. He quoted the principles laid down by Lord Deas in a case very much on all fours with the present one. Lord Deas pointed out, first, the unpremeditated nature of the attack; second, the prisoner's habitual kindness to his wife, except when he was the worse for drink; third, there was only one blow or stab; fourth, the prisoner was of peculiar mental constitution, had had his mind weakened by successive attacks of disease, had probably had sunstroke followed by epileptic fits. "If weakness of mind could be an element in any case in the question between murder and culpable homicide, it seemed difficult to exclude that element here." Following on this charge, the jury returned a verdict of culpable homicide, and the Lord Justice Clerk, following the precedent laid down in the former case, sentenced the prisoner to ten years' penal servitude. To the medical mind this seems rather illogical. If the prisoner was insane on the occasion of the act (or acted under an insane impulse), surely a criminal lunatic asylum is his proper place. It seems a little unfair on both the public and the prisoner to send him to a jail for ten years, after which he will be released, presumably as dangerous to the community as heretofore.

Edinburgh Hospital for Women and Children.—The annual meeting of this institution, which is staffed entirely by medical women, was held last week. The in-patients for the year number 179, the out-patients 2,451. The arrangements of the hospital and dispensary have always included a substantial contribution by the patients towards the cost of their treatment. During the year nearly £300 has been received from this source. That the finances of the hospital are in a satisfactory state is shown by the fact that the institution has been able this year to pay off half of the bond for £1,000 remaining over the hospital. The revenue was £1,439, the expenditure £1,165. Mrs. Basil Orr, M.B., Ch.B., has been appointed anæsthetist and clinical pathologist to the hospital.

BELFAST

Death of Dr. A. S. Merrick.—On December 19th, at his residence in Belfast, Dr. Alexander Stewart Merrick passed away after a long illness. He was born in Cork sixty years ago, and educated in that city, passing through Queen's College with great distinction. After graduation he was appointed assistant medical superintendent of Cork Lunatic Asylum, and in three years was promoted to the office of medical superintendent of the Donegal Asylum at Letterkenny. In 1875 he was transferred to the charge of the Belfast and District Asylum, where he remained till he retired on pension in 1897 on account of failing health. He had been highly myopic for years, and latterly became nearly blind, as well as feeble in general health. He succumbed to cerebral hæmorrhage in the end.

Dr. Merrick was a most kindly and amiable man, a true Irishman of the best type, and was highly respected by all who came in contact with him. Many medical men trained in the Belfast school passed through his classes in Mental Diseases at the Belfast Asylum, and there are few who will not look back with pleasure to those warm afternoons in the summer session when the lectures were enlivened with a fund of native wit and of shrewd common-sense which were so characteristic of the man. Dr. Merrick leaves a widow, a daughter and three sons. The eldest son, Dr. Warren Merrick, has adopted his father's profession.

LETTERS TO THE EDITOR.

MEDICAL CLUBS.

To the Editor of the Medical Press and Circular.

Sir,—"A joint meeting of the Liverpool and Birkenhead Divisions" was recently held in the Liverpool Medical Institute to consider an amended report of the sub-committee appointed to "investigate the Liverpool Municipal Guild Medical Insurance Society," whatever that is! "All resident medical practitioners resident in the district are invited to be present," so ran the summons.

For the first time the resident practitioner is aware that the members of the B.M.A. are endeavouring to get up a club comprehensive enough to swamp the half of the profession! There is no limit to the "Guild"—its members may be legion, and the sub-committee propose to accept these members at :—

"Males—6s. per year for those not earning more than £120 a year.
,, 8s. 6d. per year for those earning between £120 and £150 per year.
Females—7s. per annum for those not earning more than £120 per annum."

"Proportionately higher terms shall be arranged for higher salaries," *e.g.*, the Lord Mayor would be on a higher scale!

The Guild considered these terms too high, to which the B.M.A. replied in a prolix letter that they are not in possession of all the facts!

At this point in the meeting someone asked the Chairman what *locus standi* he had, as he had been invited here to listen to negotiations he had no business with; could he vote and speak? "Yes," was the reply, which gave rise to some dissent. "It would be all right if recorded on the minutes!" was one interjection. "It was usual for this association to invite outsiders, as a sprat often caught a whale," was given in apology by another. The latter remark was considered too honest, and was ruled out of order.

A member then commenced on the philosophy of the situation, and related how he and other two of the members attended to a club at 1½d. per head, which he did not consider a profitable undertaking. From this it was inferred that the number of visits required by the Guild might bring the medical profession to the same level, if not a little lower. It was finally resolved to close this ordinary meeting of the Joint Divisions with a postliminium in order that a reconciliation or entente cordiale might be established. What are we to conclude from these proceedings?

I am, Sir, yours truly,
A Resident Medical Practitioner.

STAG-HUNTING AND VIVISECTION.

To the Editor of The Medical Press and Circular.

Sir,—More terror, pain, and lingering torment are inflicted upon helpless animals in a single day's battue than is caused in all the physiological laboratories in the kingdom in a whole year. Besides this form of sport there are the numerous varieties described by the Rev. J. Stratton in the Medical Press and Circular of this date. Among the noble promoters of these sports are to be found some of the most influential and wealthy of the patrons of anti-vivisection, such as Lord Llangattock, the Duke of Portland, and Colonel Lockwood. In my letter which appears beside the Rev. J. Stratton's, I have spoken of the harm to the suffering poor to which the fanatical abuse of the profession by anti-vivisectionists is giving rise. Can this Christian minister not take the trouble to ascertain at first hand the facts about experiments upon animals, and in the meantime direct his further energies to the gross and unjustifiable forms of wholesale cruelty he rightly denounces. Physiologists and pathologists throughout the world are agreed that the progress of science depends upon experimentation upon animals; and they affirm that the amount of pain they inflict is literally infinitesimal compared with that occasioned by the use of lower animals in the service, and the feeding of mankind. In these latter directions the greater part of the suffering could be done away with without in the least detracting from the advantages to mankind. There is surely room here for the energies of all the anti-vivisectionist societies. Why they do not recognise this fact seems inexplicable.

I am, Sir, your truly,
S.

Reigate, Surrey, December 26th, 1906.

THE CANCER PROBLEM.

To the Editor of the Medical Press and Circular.

Sir,—Mr. Edmund Owen, in his Bradshaw Lecture on "The Modern Treatment of Cancer," observes, "In the world of therapeutics there are still dark tracts and continents which can be discovered only by men of imagination and energy; and possibly the Columbus or the Raleigh is to-day with us, who later on will bring back the glad tidings that he has found out the nature of cancer and can tell us of its cure."

Now doubtless that possible Columbus or Raleigh would individually be the happiest, and would be acclaimed as the greatest of men, but would he do a real service to humanity in general? I make bold to doubt it.

What is a cure? It may be defined as some agent which when introduced into, or made to react on the body, neutralises at the least or destroys at the most the products of a morbid process, the cause still persisting. In other words, the results of insufficient knowledge or wilful negligence of the laws of nature, can be nullified by some stronger power. A cure therefore would enable mankind to persist in the courses which lead to disaster, but indemnify themselves against it. Is such a consummation possible, or to be desired? Obviously the better course is to acquire the knowledge and avoid the negligence. A formidable bar to progress in that direction is the present-day assumption that cancer differs in kind and not merely in degree from other diseases. This probably is due to the quicker and greater formation of new tissue in the cancerous process. But is there any diseased process in which new tissue is not formed? Will anyone assert that the nasal or gastric mucous membrane is in the same position structurally after an attack of catarrh as before? No, beyond doubt there is no such thing as functional disease.

If there is no cure, in the sense above indicated, for such mild maladies as nasal and gastric catarrh, how then should we expect one for cancer? But is prevention not nearer at hand, and easier?

Let us turn to the Bradshaw Lecture for guidance in this direction. Dr. Dawbarn's "Method of Local Starvation" surely conveys a hint. If, as he asserts, —as others have before him—that cutting off the local nutriment leads to atrophy of the product of the cancerous process when actually present, or "to control of malignancy" when it has been removed, surely a general diminution of nutriment to the organism as a whole would tend towards its prevention.

In other words, if the supply of nutriment to the body were sufficient for its normal growth alone, there would be no possibility of abnormal growth occurring, and no need for it. Sir William Banks held that cancer was a disease of "repletion." The inference is obvious. Let mankind endeavour to find out that kind of nutriment, and that amount of it, necessary to normal growth, and there will be no necessity to discover a "cure" for abnormal.

Finsbury, Dec. 28th, 1906. I am, Sir, yours truly,
Hope Grant, F.R.C.S., Eng.

SLEEPING SICKNESS.

To the Editor of The Medical Press and Circular.

Sir,—Many statements have lately appeared in the press to the effect that Dr. Koch has at length discovered, in the compound of arsenic known as Atoxyl, a cure for sleeping sickness. I should like to say that this drug was first suggested and experimented with for the disease by Dr. Wolferstan Thomas, of this school, two years ago; that ever since then we have continued our study of it; that its complete efficacy has not yet been proved; and that premature announcements on the point are to be deprecated.

I am, Sir, yours truly,
Ronald Ross,
Professor of Tropical Medicine, University and School of Tropical Medicine, Liverpool.

SAUCEPAN AND APPENDIX.

To the Editor of the Medical Press and Circular.

Sir,—Referring to the annotation in the last number of your journal, I may mention that only a few days ago an intelligent cook showed me how the enamel scales off in a badly enamelled cheap saucepan. It seemed to me no difficult matter to understand how the use of such a faulty cooking vessel might spread sharp gritty particles broadcast in the food, and so create a degree of intestinal irritation likely to cause appendicitis. More evidence is, of course, needed to establish the connection so clearly put before the Medical Society of Birmingham by Sir James Sawyer.

I am, Sir, yours truly,
John C. Thorowgood, M.D., F.R.C.P., Lond.
Bognor, Dec. 28th, 1906.

OBITUARY.

MR. R. P. LAWSON, L.R.C.P.LOND., M.R.C.S.

BY the death of Mr. Lawson, of Higher Openshaw, a well-known Manchester citizen has passed away. He had an extensive practice in the district, and was a warm supporter of all charitable movements. Deceased was a comparatively young man, having obtained his diploma in 1893.

WILLIAM TRAVERS, M.D., F.R.C.S.

We regret to record the death of Dr. William Travers at Kensington, where he had practised for 40 years. He was one of the senior Fellows of the College of Surgeons, and took his M.D. of Durham University in 1879. He was the first resident medical officer appointed to Charing Cross Hospital, when he took office there in 1860. In 1866 he moved to Kensington, where he practised until his death. He was physician to the Chelsea Hospital for Women from 1883 to 1894. Dr. Travers was well known to the various societies connected with his profession.

MR. HERBERT W. KENDALL, F.R.C.S.

We regret to announce the death of this gentleman, who died at his residence, Burlington Road, Bristol, on December 22nd. A few days previously he had undergone an operation for appendicitis, and things appeared favourable until an attack of pleurisy supervened. The immediate cause of death, however, was from a blood clot. Mr. Kendall was a native of Gloucestershire, having been born at Bourton-on-the-Water, near Cheltenham. As a student at the Middlesex Hospital he earned a high reputation, having filled the offices of House Surgeon and Obstetrical Assistant with much credit. Only lately he had taken a new residence at Bristol, and his premature death just as he was acquiring an excellent practice is a matter of deep regret. A widow and three children are left to lament his loss.

DR. ANDREW BALFOUR, J.P.

DR. BALFOUR died suddenly on December 26th from heart failure. In him the community among whom he laboured has lost one of its most useful members. He was born in Hong Kong in 1852, and settled in Portobello as an assistant to his father in 1873. Since his father's death twenty years ago he has been in partnership with his brother, Dr. John Balfour. Dr. Balfour has taken a prominent share in the public life of the community. He was medical officer of health for Portobello until it was merged into the Edinburgh city area, and was also medical officer under the Duddingstone, and subsequently under the Edinburgh Parish Council. In 1877 he founded the Portobello Working Men's Institute, and took an active interest in the reading and recreation rooms at the adjacent village of Niddrie. He was a keen politician, and held high offices in the local Conservative Association and Union Club. How many-sided his interests were may be gathered from the fact that at the time of his death he held about 30 appointments, which, with the exception of his professional ones, were of an honorary nature. He leaves a widow, three sons, and a daughter to mourn him. He will for many a day be missed from and remembered in the borough of Portobello.

OUTBREAK OF ANTHRAX IN SOMERSETSHIRE.—A serious outbreak of anthrax has occurred at Chew Stoke. The disease broke out on a farm where the carcase of a cow, which had died in an adjoining district, had been boiled up for feeding purposes. Three people who have handled the carcase are ill, and stringent measures have been taken to prevent the spread of infection, and to stamp out the disease.

REVIEWS OF BOOKS.

MOOR AND HEWLETT'S APPLIED BACTERIOLOGY (*a*).

IN bringing out this new edition of his book, "Applied Bacteriology," Mr. Moor has been fortunate in securing the assistance of Professor Hewlett, and we may say at once that the work is a great advance on what it was in its first and second editions. It is obvious that no one not thoroughly *au fait* with bacteriology in all its practical developments in relation to disease can write a satisfactory book on the subject, but now that he has enlisted Professor Hewlett's help Mr. Moor has turned out a serviceable manual. The difficulty in preparing a work of this kind is the terrible one of deciding what out of a mass of material, formed, unformed, and in process of formation, should be included and what left out. Bacteriology is an almost impossible subject to deal with sufficiently in its present stage of development, so multifarious, contradictory, and confusing are the various observations on the subject. It is, then, hard to blame the authors for not treating some important questions at greater length, and for not giving a more complete criticism of results arrived at, for we know that to have done so would have meant curtailing the rest of the descriptions. But it is somewhat open to question whether the plan of the work is not too large for a handbook. The two chapters that follow the introduction are devoted to bacteriological apparatus and methods of bacteriological study, and they are of the practical character one expects from laboratory teachers. Then the general questions of the methods of spread of diseases, immunity, bacterial products and serum-therapy are discussed clearly and comprehensively, and thence the reader is carried on to the consideration of the specific bacteria of the various diseases. The protozoa and parasitic fungi are next described, and then follow some sections on certain diseases of animals and plants and certain diseases of man not dealt with previously. Afterwards we pass to what we consider the most satisfying part of the work, namely the chapters on fermentation, disinfection, and the bacteriology of water. Indeed, the chapter on disinfection and disinfectants is particularly good, and we could only wish that its teaching would penetrate into the bosoms of those who buy and those who sell disinfectants. For the student reading for the D.P.H. this book should be even more valuable than it has been in the past, and its previous success testifies to the estimation in which it has been held. Among the features that deserve the highest commendation are the coloured bacteriological plates. These are of great beauty and accuracy, and represent the cultural characteristics of the various organisms with astonishing fidelity.

RATIONAL ORGANOTHERAPY. (*b*)

THE volume on "Rational Organotherapy," which lies before us is described as the first, but we do not quite understand if it is the first of a series on organic remedies, or if it is to be followed by a second on the same subject. For it is almost exclusively occupied by the consideration of spermin and its effects on metabolism and tissue-resistance, as studied by Professor von Poehl. The book is none the less interesting for being the work of an enthusiast, and that Professor von Poehl certainly is. Indeed, he has been the chief worker at the subject for some fifteen years, and his belief in his theory and its success in practice

Moor M.A.Cantab., F.I.C., formerly Public Analyst for Exeter, and Senior Demonstrator in Public Health, King's College, London, with the co-operation of Richard Tanner Hewlett, M.D., F.R.C.P., D.P.H., Professor of Bacteriology, King's College, London. Third Edition. University Series. London: Bailliere, Tindall and Cox. 1906. 12s. 6d. net.

(*b*) "Rational Organotherapy with Reference to Urosemiology." By Prof. Dr. A. von Poehl, Prof. Prince T. von Tarchanoff, Dr. Alf. von Poehl, and Dr. P. Wachs. Translated from the Russian text. Vol. I. London: J. and A. Churchill.

seems to grow stronger with time. It is certainly well worth a medical man's while to make himself acquainted with the scope and range of spermin as here described, for not only does its employment rest on a scientifically conceived theory, but the therapeutic results obtained clinically also seem well established in fact. Spermin is an organic body which has been found by von Poehl in all the tissues, and he believes it to be a product of the decomposition of nuclein. Now the invasion of a part by bacteria is followed in normally active tissues by leucocytosis, and if the blood is of due alkaline reaction, the destruction of the leucocytes is accompanied by the release of soluble, active spermin. Spermin is said to have the power of greatly increasing tissue exchange with oxygen (textural respiration), and consequently the vital activity of the part is much enhanced. Spermin, moreover, by promoting this internal respiration, is also useful in auto-intoxication, for it helps rapidly to transform leucomaines that are clogging the tissues into soluble bodies that can be removed by the blood-stream. Spermin, in fact, is a ferment of the class "katalysator," that is, one able in infinitesimal quantities to promote or retard a reaction, without itself suffering any loss of weight. Von Poehl's studies have taken a wide range, and he has diligently pursued his object, the elucidation of the action of spermin in every direction, and we are sure that his book, for its variety and interest, will well repay anyone who reads it, quite apart from the importance of the subject itself. It is somewhat odd that a book which is not only well but even idiomatically translated, should contain words such as "octaëders," "baryt," "clysma," and many similar ones which jar ungracefully on the British medical ear.

TROPICAL DISEASES. (a)

"Lectures on Tropical Diseases" by Sir Patrick Manson need no other commendation to the English-speaking world than their title. They recommend themselves. For not only is Sir Patrick the very Hippocrates of tropical medicine, but he writes with tha vivacity and speaks with that fluency which carries the student along *nolens volens*. The facts that stand out in all his writings are that he is in deadly earnest, and that his past researches and victories are as nothing to what remains to be done, and what he means to do. So these Lane Lectures delivered at San Francisco last year may truthfully be said not only to mark the soundest views on the latest questions of tropical pathology, but also to leave the reader wondering how it is possible for a man of the lecturer's engagements to keep himself so thoroughly posted in the last details of research. In view of the catastrophe that wrecked San Francisco since the lectures were delivered, it is not a little curious to read the prophecies made at their inauguration "It takes little prescience to foretell that ere many years have passed, thousands will annually leave your shores for tropic (*sic*) countries, and thousands will return to them from tropic exile. San Francisco will become a yet greater commericial centre, and will stand in this respect to the west of the American continent very much in the same relationship as London used to stand to the west of Europe. The San Francisco of to-day is but a village as compared to the vast metropolis of the Pacific which it is her destiny to become." So, indeed, may it yet be!

But the real interest of these lectures lies in their clear, definite, and—if the word has not grown opprobrious—dogmatic teaching, and in the happy illustrations, culled from Sir Patrick Manson's rich experience, which emphasise his points. "Personally, I have never seen a malarial fever which has altogether resisted the proper use of quinine, provided the case has not already passed into a hopeless condition." "Any fever which persists unmodified after forty-eight hours' dosing with quinine, is not a malarial fever." "In this way, the filaria passes from man to man, and in this way (*i.e.*, by mosquito-transference) the elephantoid diseases are acquired and communicated. The knowledge is a sure and certain guide to efficient prophylaxis." These quotations are typical examples of the firm rocks which peep out among the shifting sands of theory and conflicting views, and which will make this book of real value to the enquirer. His interest, too, will be kept agog all the time by the clinical cases quoted, and he will respect Sir Patrick Manson all the more because he does not mind "giving himself away," and, when he can do so anonymously and without malice, his friends. His story (page 172) on the value of serum-diagnosis in Malta Fever, for instance, is as amusing as it is "teaching." We cannot say more for the volume as a whole than it is so interesting that we forget we are not reading a novel.

CLINICAL ANATOMY. (a)

The authors of "Clinical Applied Anatomy," Dr. Box and Mr. Eccles, have themselves set the standard by which they wish to be judged, for they open their preface by saying: "In 1862, there appeared a work which is now classical, 'Rest and Pain,' by John Hilton. In the preparation of the present volume we have endeavoured to follow, in some degree, the lines suggested by that author." Now "Rest and Pain" was one of the early attempts, like Sir Charles Bell's "Hand," to clothe with life the dry bones of anatomy, and Hilton succeeded as no one before or after him has succeeded in raising anatomy from the region of drudgery and mnemonics into the realms of poetry. But then Hilton brought to his task not the unimaginative mind of the formal anatomist, not the confined outlook of the student's mentor, but a degree of sweetness and light pecular to his artistic and spiritual nature. To follow Hilton, then, demands a particular type of temperament in which philosophy blends with utility, and utilitarianism finds no place, and such a disposition would be an ill equipment for a modern hospital physician or surgeon who has to nurse his students through exams to get a reputation as a "teacher." We may say at once that the present volume is as different from Hilton as the second and third parts of "Henry VI." are from the rest of Shakespeare; but that is not to deny that the work has an important function. It is curiously unequal; some parts, such as the section on the nervous system, on the malformations of the heart, and on hernia, being excellent, whilst others are of a distinctly lower order of merit. On the whole, we should describe the book most accurately by saying that it seeks to show the mechanism of disease, that is to say, it endeavours to explain why certain symptoms are produced in certain disorders, and how such symptoms are ultimately dependent on the anatomical conformation of the parts. The idea is good, especially in combining surgical and medical anatomy together, and no doubt the book will be largely read among students. They perhaps may not notice a good deal of the loose writing which frets the reviewer's eye. We might at any rate be spared such idiomatic expressions as "the right Poupart" (page 377), or such inelegancies as "almost always a much milder and usually uncomplicated disease" (page 50), and "pulmonic" (page 10). It is a pity that so useful a book and one which we take it is destined to be largely in request at two great hospitals was not a little more carefully edited. But there is much to praise in it, and its aim and somewhat original bent are highly to be commended.

TRANSACTIONS OF THE ROYAL ACADEMY OF MEDICINE. (a)

THIS volume contains the papers read before the various sections of the Society during the year, as well as abstracts of the discussions on these papers.

We notice that an innovation was made last session, in that two evenings were devoted to general discussions on "The Diagnosis, Treatment, and Pathology of Empyema," and "Abdominal Tuberculosis." At these meetings papers were read by surgeons, physicians, and pathologists, treating the subjects from their different aspects; judging by these papers and the discussions which followed them, these two meetings must have had a considerable interest for all branches of the medical profession, and the idea of bringing together surgeons and physicians for the consideration of subjects more or less within the province of both cannot fail to be of advantage in these days, when such a tendency exists for the sharp demarcation between the two main divisions of the profession.

In the Section of Medicine is a paper of special interest on "Myelogenous Leukæmia and its Treatment." A very full clinical account of a case is given, accompanied by illustrations, charts, and tables. The main interest of the case lies in the fact that after remaining in hospital for over six months, and undergoing X-ray treatment, the patient left the hospital apparently cured. The leucocyte count, which on admission was 260,000, had fallen to normal, and the spleen had decreased more than 3 ins. in size. Among the papers read before the Surgical Section are two on "Sterilisation of the Hands"; both of these are founded on extensive bacteriological experiments. The results are surprisingly different. One observer found infection with both pathogenic and non-pathogenic organisms in nearly 40 per cent of the tubes inoculated; the other found a little over 3 per cent. of infection, and only with non-pathogenic microbes. Though the method of sterilisation varied in the two cases, this seems scarcely sufficient to explain the enormous difference in results.

A successful case of partial gastrectomy for supposed malignant ulcer is recorded; but on microscopical examination this was found to be a case of indurated inflammatory thickening around an old-standing ulcer. This case emphasises the great difficulty of making a differential diagnosis in these cases, even when the parts are exposed to view at operation, though some operators who have had considerable experience profess to be always able to recognise which condition is present.

In a paper on the treatment of Acute Peritonitis, the author very rightly advises against the use of morphia, unless a definite diagnosis has been made or a decision arrived at that operative treatment is or is not necessary. As regards the vexed question of the best method of removing foreign matter and exudation from the peritoneal cavity, the author's advice appears to be to rely on sponging only in cases of localised collections, but that in cases of generalised peritonitis free flushing with saline solution should be employed. The author also points out the fallacy of attempting general drainage of the peritoneal cavity owing to the rapidity with which adhesions form. Local drainage in the case of localised peritonitis is, of course, essential, and here the formation of adhesions is one of the objects most desired, in order to shut off the rest of the cavity from infection. But in the case of general peritonitis adhesions form around the drain, no matter what material is used, within the first twelve hours, so that the drain becomes purely local. The only exception to this is probably in the case of the pelvis, where there is a definite cavity in which fluids tend to accumulate, especially if the half-sitting-up posture is adopted. The advantages of copious saline injections are also touched upon.

Another paper of interest is one on "A Further Series of Enucleations of the Prostate." This series consists of eighteen cases with five deaths.

In the Obstetrical Section, will be found a paper on "Two Years' (Major) Operative Gynæcology in the Rotunda Hospital," also the Clinical Report of this hospital for the year.

In the Section of Pathology are numerous papers of great interest, some of which are illustrated. Among these we may mention the following:—"An Unusual Tumour of the Kidney," "A Case of Melanuria," and "Urticaria Pigmentosa."

(a) *Transactions of the Royal Academy of Medicine in Ireland.* Vol. XXIV. John Falconer, 53, Upper Sackville Street, Dublin. 1906.

DISEASES OF THE DIGESTIVE SYSTEM. (a)

THIS is no hackneyed treatise on the disorders of digestion, for the author asserts his individuality by attacking many things held in almost sacred esteem by practitioners: such beliefs for instance as that tea rapidly infused contains just as much tannin as tea left standing. He asserts that boiled milk is more digestible than plain milk, and that whiskey is obnoxious as a table beverage, and he throws cold water, metaphorically speaking, on the peptonisation of milk; he even goes the length of denying that its digestibility is thereby in any measure facilitated, though he would hardly deny that under no circumstances can peptonised milk be made to coagulate into the large hard curds formed in untreated cows' milk. On the other hand, we are told that "the use of liqueurs is justified after meals by their acting as stimulants to the muscular wall of the stomach"—a pronouncement for which many sinners will be very grateful.

Even more startling is the author's indictment of medication, having in view intestinal antisepsis, and he gravely declares that there "never was any ground in the antiseptic system of surgery" for such an attempt. Well, nobody ever suggested that there was, and the filiation of ideas would take us to Pasteur, the putative father of the germ theory of disease, rather than to Lister. But the fact that we cannot kill *all* the germs is hardly an argument against the use of intestinal antiseptics, for we may render the *milieu* more or less unsuitable short of killing anything; moreover, the excellent results that follow this medication can with difficulty be explained as merely coincidental.

The phraseology is occasionally a trifle obscure, as, for instance, when we are told in reference to the treatment of gastritis that "unfortunately the usual practice is to treat the gastritis more or less successfully . . ."; or when we are advised to dilute our wine with "mineral water"—any mineral water, apparently, chalybeate, alkaline, laxative, or what not.

We are quite touched to see our old physiology friend, Alexis St. Martin, referred to so often; we had thought he was dead and buried; indeed, this and the reiteration of explanations of ordinary terms, "atony, want of tone," and the like, suggest that the author was anxious to be understanded of the people as well as of the profession. Very much on a par with this is the solemn pronouncement that "the radical treatment of cancer of the stomach is undoubtedly surgical," and the statement in respect of secondary gastric dilatation that "surgery" is "ready and able" to effect a cure.

But these, after all, are minor if irritating blemishes, for the work as a whole is a sound practical guide to the dietetic and medicinal treatment of diseases of the digestive organs, winding up, as it does, with a list of well-known formulæ from the hospital pharmacopœia. As these diseases and disorders constitute a very large part of the general practitioner's work, the author, with his wealth of experience, is sure of an appreciative audience.

(a) "The Treatment of Diseases of the Digestive System." By Robert Saundby, M.D., F.R.C.P., &c., Professor of Medicine in the University of Birmingham, &c. London: Charles Griffin and Co. Ltd. 1906. Price 3s. net.

WEEKLY SUMMARY OF MEDICAL LITERATURE, ENGLISH AND FOREIGN.

Specially compiled for THE MEDICAL PRESS AND CIRCULAR.

RECENT MEDICAL LITERATURE.

The Treatment of Bronchiectasis.—Chaplin (*The Practitioner*, December, 1906) discusses the various forms of treatment which have from time to time been advocated for this complaint. He is of opinion that the onset of fœtid expectoration is in almost every case the starting-point of the course downward, and the aim of the physician must be to adopt methods of treatment to ward off this onset. For this purpose he has for some years past adopted the inhalation of creosote vapour with very considerable success. For the purpose of this treatment a small room about seven feet square is used, to which only a limited amount of fresh air is allowed access. In the centre of the room a fairly deep enamel dish, with five or six ounces of creosote, is placed, and under this is placed a lighted spirit lamp. The creosote vapour is driven off from the dish, and when the room is fairly thick with the fumes the patient enters, and remains in it for from twenty minutes to an hour. The patient's eyes are to be protected with watch-glasses, and the nostrils stopped with cotton-wool. The treatment is continued daily for about three months, and after that bi-weekly sittings are given. Chaplin states that he "has never met with a case unable to take the treatment, out of an experience of over a hundred cases treated." As regards results, only three of his cases have failed to be improved, while in the vast majority the improvement was most marked, the fœtor ceasing in almost every case, and in many not returning after long periods of time. K.

Treatment of Sunstroke.—Captain Foulds (*Journ. R.A.M.C.*, December, 1906) advocates the use of iced water enemata for this condition. Foulds points out that the treatment usually recommended of ice-packs is very difficult to carry out in India owing to the difficulty of getting large quantities of ice, and the statistics in that country show a very high mortality from sunstroke. Thus, in 1903, 307 cases were admitted to hospital, of which 54 died, besides which there were 15 deaths recorded out of hospital. During that year Captain Foulds had nine cases of sunstroke admitted to hospital, all of which were treated with repeated enemata of ice water and all recovered. Foulds recommends that an enema of about two pints should be given and repeated every ten minutes till the axillary temperature falls to 102 degrees F. K.

Accidents Following Thoracentesis.—Sears (*Amer. Jour. Med. Science*, December, 1906) reports four cases in which pneumothorax resulted from this operation, and suggests that the complication is more frequent than is generally believed. He also reports a case of sudden death following the introduction of a needle into the chest for the purpose of aspiration. The patient was a man, æt. 49 years, who had an effusion in the left side of the chest reaching to the third rib. On the day after admission to hospital, sixty-four ounces of bloody fluid were removed by aspiration, but the fluid re-accumulated, and three weeks later a second attempt at aspiration was made. The operation produced no mental perturbation, but when the needle was introduced he almost immediately collapsed, became cyanotic, and almost pulseless. All efforts at stimulation failed; he became unconscious, and died fifteen hours later. Only a partial post-mortem examination was allowed, and the brain was not examined. The left pleural cavity was found to contain a considerable quantity of blood-stained fluid, and the left lung was much compressed. Numerous tubercles were found scattered over both parietal and visceral pleura, both of which were considerably thickened. The heart was normal, but the kidneys showed acute glomerular nephritis. Sears does not offer any explanation of the death of this patient, though from the condition of the lung and its position, he is unable to accept the explanation which Russel has given of similar cases. From a careful study of three cases reported by him, and also from experiments on animals, Russel has concluded that the sudden syncope is due to afferent impulses conveyed to the medulla along the vagus nerve, whose terminal fibres, rendered unduly sensitive by compression or inflammation, are irritated by the needle. Sears points out that in his case it is hardly possible that the exploring needle could have reached the pulmonary branches of the vagus, since the two surfaces of the pleura were separated by a considerable layer of fluid. K.

Favourable Influence of X-rays on Chronic Bronchial Affections.—Schilling (*Mün. Med. Woch.*, 1906) had occasion to examine a patient with severe bronchial asthma, and used the X-rays to determine the exact status of the air passages. The patient found that his asthma was favourably influenced by the fluoroscopy, and Schilling thereafter applied the X-rays systematically in a large number of cases of chronic bronchitis and bronchial asthma. He tabulates the results as determined by the amount of sputum. In one case it dropped from 150 c.c. to 80 c.c. in three days after the X-ray exposure. Another patient, a man of 62, had been coughing and expectorating for months. The day before the X-ray exposure the amount of sputum was 170 c.c., the day following 140, then 110, 50, and decreased to 40 c.c. by the sixteenth day, and expectoration had entirely ceased by the end of the fifth week. In every instance the amount of sputum dropped nearly one-half the day after the exposure, and progressively declined thereafter. Every patient was favourably influenced, and the improvement or the complete cessation of the expectoration and asthma persisted for months. He suggests as explanation of the unmistakable and prompt benefit derived that possibly the proliferating cells of the microscopic glands in the bronchi react to the rays, similarly to the effect observed in X-ray treatment of hypertrophied prostate, lymphoma, goitre, etc. The extreme permeability of the lungs for the X-rays aids in the process. He used a 30 c.m. inductor, the patients were seated, and the exposure was made from two, four, or more directions, at the points where the rattling was most pronounced, avoiding those where the muscles were especially thick. The unexposed parts were protected against the rays, and the exposure lasted from 10 to 15 or 20 minutes, the distance from the tube being about 15 c.m. The total of the exposures was kept within the range of the maximal dose, and only a single sitting was given. Notwithstanding the unmistakable relief from excessive bronchial secretion and from the tormenting asthma, Schilling reserves his opinion in regard to the actual therapeutic value of X-ray treatment of bronchial affections until he can speak from a larger experience. D.

Alcohol in the Nutriment of Diabetics.—Benedict and Sörök (*Zeit. f. Klin. Med.*, 1906) attempt to show by substituting alcohol for a part of the food fat whether the acetone in these cases is derived from the fat. They find in diabetics that the acetone excretion is reduced by this alcohol substitution, but in non-diabetics there is little effect. In some cases there is also a decreased glucose and nitrogen excretion. In the metabolism of healthy individuals alcohol can replace proteids, but less effectively than is done by carbohydrates and fats. On the other hand, in diabetics alcohol seems more effective in replacing the proteids in metabolism than is the case with the fats and carbohydrates. These observations justify the use of alcohol in the diabetic dietary. Contra-indications for its use are albuminuria, neuritis, arterio-sclerosis. It should not be used in diabetes occurring in childhood. D.

Ring Test for Acetone.—Lange (*Mün. Med. Woch.*, 1906) has modified the Legal test and rendered it simpler and more reliable by substituting ammonia for the sodium hydrate. This avoids the disturbing creatin reaction. The urine (15 c.c.) is treated with glacial acetic acid (.5—1 c.c.), and then with a few drops of a freshly prepared solution of sodium nitroprusside; a few c.c. of ammonia are then cautiously poured on top of the mixture. In case of the presence of acetone, a bright violet ring appears at the point of contact. The violet ring grows brighter and brighter without spreading wider, irrespective of the quantities used in the test tube. Acetone .025 per cent. is readily detected by this test. Alcohol and aldehyde do not give the reaction. D.

Treatment of Hyperchlorhydria.—Rebizzi (*Gaz. deg. Ospedali Milan*, 1906) describes his experiences with eight patients with hyperchlorhydria, taking a test meal nearly every day with examination of the stomach contents. They were treated with glucose, atropine, or a mixture of equal parts of tinct. stramonium, belladonna and hyoscyamus, the dose of the latter being 20 drops morning and night. The effect of the last two was most excellent in the cases of primary hyperchlorhydria associated with gastric ulcer, and dubious in hyperchlorhydria associated with neurasthenia. The glucose did not seem to produce much effect. D.

The Heart in Acute Infections.—Ortner (*Zeitschrift für Heilkunde*, Bd. xxvi., H2.) has studied the circulatory system in a large number of typhoid patients, and finds in most of them accentuation of the aortic sound, dicrotism, irregularity, well-filled arteries, and a pulse of good amplitude. In some cases also he noticed a dicrotic capillary pulse in the finger-nails. He regards these phenomena as due to increased effort on the part of the heart, secondary to a toxic relaxation of the peripheral vessels. As Weisel's investigations have shown, there occurs in the peripheral arteries not only a toxic loss of tone, but also severe anatomical changes in the elastic tissues of the vessel wall. Similar changes may be found in other infective diseases, such as influenza and pyæmia. As long as the heart responds in the proper way to these peripheral changes, by augmenting the force of its beat, the prognosis is good, and this can be determined clinically by observing that the aortic second sound is louder than the pulmonary. When the pulmonary is the louder of the two, the prognosis is less favourable. M.

Narcolepsy. — Blodgett describes an interesting example of this condition (*Amer. Journ. Med. Sci.*, August, 1906). The condition consists of a sudden and irresistible inclination to sleep, coming upon an individual outside the hours usually passed in slumber, and appearing with a more or less regular periodicity. It is generally found in persons suffering from the arthritic diathesis, or during the course of the different auto-intoxications. The cause at work in the present case is supposed to be a syphilitic infection transmitted to the third generation, the evidence in favour of this being that all the members of the second generation presented well-defined symptoms of hereditary taint, and that many members of the third present similar stigmata. The patient is a woman, æt. 65, who first noticed at the age of 22 that she was subject to periodic and frequently returning attacks of somnolence. The attacks come on at all times of the day, and on awaking the patient is usually unaware that she has been asleep. Her sleep at night is good, and her general health excellent. Latterly it has been thought that her mental powers show some sign of deterioration. Occasionally a whole day is passed in rapidly following sleeping periods. The patient can always be easily aroused, and never presents any signs of mental confusion. M.

Hæmophilia.—Muir places on record a family in which bleeders have been known to exist during the last eight generations (*South African Med. Rec.*, Oct. 25th, 1906). The earliest case occurred in a male who was born in 1783. This individual died from epistaxis. He had five healthy sons, and four daughters. Of the daughters, two had healthy children, and two had hæmophiliac sons. One of these sons had six healthy male children, and two daughters, both of whom transmitted the condition to their male children. The writer refers also to numerous collateral branches of this family in which instances of bleeders were known. He also calls attention to the fact that the disease seems to have been twice handed on by the male line—namely, from the first to the second generation, and from the fourth to the fifth. In the present generation, the eighth, at least seven cases have already come under the writer's notice. M.

Arsenic in Diabetes.—Monsieur Verdalle writes on this subject (*Archiv. Gen. de Méd.*, March, 1906), and comes to several important conclusions with reference to the use of arsenical waters. These may be summarised as follows:—(1) Arsenical hydrotherapy is useful in all forms of diabetes, but especially in that form which is ascribed to hyper-activity of the liver. (2) Albuminuria is no contra-indication to the use of arsenic. (3) The result of a course of treatment is that in most cases the glycosuria completely disappears, and the excessive nitrogenous excretion also diminishes *pari passu*. (4) The general health is also enormously improved, and in no case have any signs of poisoning by the arsenic shown themselves. (5) The existence of anæmia, skin complications, and pulmonary trouble is an additional factor in rendering the use of arsenic of the greatest importance, if any improvement is to be gained; but the less complicated the case and the earlier it is got under treatment the better the result. M.

Mast Cells in Leukæmia.—Joachim reports the post-mortem findings in two cases of leukæmia, in the blood of which during life there was an enormous preponderance of mast cells up to 56 per cent. The one case was treated by arsenic, and the other by X-rays, but in neither did any improvement take place. The autopsy showed changes in the red marrow, great enlargement of liver and spleen, and also swelling of the inguinal, mesenteric, and mediastinal glands. In all of these there were found very large numbers of mast cells, while the liver and spleen showed throughout myeloid transformation. Very numerous Charcot-Leyden crystals were found both in the leucocytes of the fresh blood and also in the pathologically altered viscera. Under the X-rays the mast cells showed less relative diminution in numbers than the other white cells; thus, though they fell absolutely from 133,000 per c.m. to 79,000 per c.m., their percentage number at the same time rose from 56 per cent. to 80 per cent. M.

A Hard Case.

Lately, Mr. W. Adamson, president of the Royal Southern Hospital, Liverpool, speaking from long experience of the work carried on at that institution, mentioned that many strange facts came to his knowledge. One that specially attracted his attention was the fate of a patient from whom there were taken in five different operations 228 plum stones, 28 cherry stones, 90 grape seeds, and 12 extras, comprising stones, nutshells, and bits of stone. A further miscellaneous assortment of odds and ends would, no doubt, have been excavated had not the patient died.

MEDICAL NEWS IN BRIEF.

Case of Anthrax.

An inquest was held at Liverpool, on December 24, on the body of a widow thirty-four years of age. The woman's son said his mother, a healthy woman, got her living by making bags for a firm of sack merchants in Liverpool. When she returned home from her work on December 17, her neck was swollen. She attended the North Dispensary, and in the evening was sent to the David Lewis Northern Hospital. The manager at the sack and bag warehouse said that, in addition to making new bags and sacks, his firm repaired bags which had held sugar and various kinds of grain, but no animal matter. The bags were all more or less of a dusty nature. The woman sewed the bags, which were classified. Those which she attended to during the week before last, belonged for the most part to a firm of millers, whilst there were also a few sugar bags, which had come from grocers' and confectioners' shops. He had never heard of a case of anthrax arising through work such as the woman had been engaged in.

Mr. Evans (Inspector of Factories) said there were special regulations dealing with anthrax, but they did not apply to sack and bag warehouses. That was the first case of the kind that he had heard of.

Dr. Byrne, of the David Lewis Northern Hospital, described the measures taken. She was admitted on the Wednesday night. A typical malignant pustule or sore was found on the neck, accompanied by a good deal of swelling. About an hour later she was operated on. She seemed fairly well all that night and during the following day. About twelve o'clock at night, however, her pulse began to weaken, and gradually failed, in spite of everything. The case was undoubtedly one of anthrax. They took a slide of the affected part prior to the operation. They examined it microscopically, and found the anthrax bacilli there in enormous numbers. This was a case of external anthrax. The woman probably had a scratch or small boil, and thus got the infection. The period of incubation was two or three days, so that she might have got the germ before the pimple appeared.

Mr. Glover, solicitor, said he had been requested by Mr. Connolly to say how sorry he was that such an accident should have happened, and that so far as the woman's son was concerned, he would do all he could to find him employment and to look after him.

The Deputy Coroner, addressing the jury, said that unfortunately there had been a good many cases of anthrax in Liverpool lately. This, however, was the first case where the disease had appeared in anybody working at a bag warehouse. It was possible that the woman had got the infection from the bags, but it was equally possible that she had got it elsewhere.

The jury returned a verdict to the effect that death was due to anthrax, adding that as to how set up, there was not sufficient evidence to show.

Outbreak of Diphtheria.

A serious outbreak of diphtheria is reported from Totley and adjacent hamlets in Derbyshire, and it is estimated that there are upwards of a hundred cases. Recently a young man named Arthur Fell, who was affected with fatal results, was buried in the dead of night, in order to avoid a congregation of people, or anything in the nature of a demonstration. When nearly everybody in the village was asleep, the carriage wended its way up to the house in which the young man had lived, and his body was brought down to a burial ground at Dore. With as little ceremony as possible it was interred there. A few days before the young man's brother died from an infectious disease, and was buried in the ordinary way by daylight, although the relatives and friends took the precaution of limiting the number of mourners. Among them was the brother Arthur, and he was stricken with illness almost as soon as he got home. It is feared that a contributory cause to the disease spreading to such an alarming extent was the disinclination of a few parishioners to take the necessary precautions when the outbreak was in its early stages.

Wholesale Lead Poisoning.

Another lead poisoning scare has occurred at Saddleworth, said to be due to the drinking of the water supplied by the Ashton Joint Waterworks Committee. The water is acid from the decomposing peat, and so dissolves the lead service pipes. At a meeting of the Saddleworth District Council, Dr. Ramsden, the medical officer of health, said hardly a day passed without his having reports as to lead poisoning. Lead poisoning was wholesale, and he would have to write to the Local Government Board if things went on this way. The consequences on the future generation would be more than he could describe. It was also stated that people were giving up the Corporation supply and going back to the springs, so great is the alarm. As regards general health, Dr. Ramsden said he had never known a time when there was such an epidemic of all kinds of diseases.

Industrial Diseases.

As a result of the labours of the Departmental Committee which has for some months past been sitting at the Home Office, under the chairmanship of Mr. Herbert Samuel, M.P., about thirty so-called industrial diseases will be added shortly to the schedule of the Workmen's Compensation Act, to which the Royal assent has just been given. Among these scheduled diseases have been already included lead poisoning; “phossy jaw, which afflicts certain people engaged in manufacture which necessitates the use of phosphorus; anthrax, to which wool workers are more or less exposed; and ankylostomiasis. Among those who have been assisting the Parliamentary Under-Secretary with expert advice are Prof. Clifford Allbutt, F.R.S., and Mr. H. H. Cunynghame, the Assistant Under-Secretary at the Home Office.

Commission on the Feeble-Minded.

At a sitting of the Royal Commission on the Care and Control of the Feeble-Minded on December 13th, Dr. E. W. White, professor of psychological medicine at King's College, said he was of opinion that the Lunacy Commission was totally inadequate for the proper discharge of its duties. The paid Commissioners on the central board should be increased by three medical members. The amalgamation of the office of Lord Chancellor's Visitor with the Commissioners would certainly be a step in the interest of economy. He was strongly in favour of local Commissioners. Dr. J. Smith Whitaker, medical secretary to the British Medical Association, said the association recommended a board of Commissioners should have the central supervision of every variety of unsoundness of mind. The placing of persons suffering from habitual inebriety and drug habits should not be made dependent upon any previous criminal procedure, but the whole procedure should be made analogous to that of the Lunacy Acts. He also recommended the removal of the disqualification on certain medical practitioners in regard to the post of Commissioner in Lunacy. Dr. A. C. Buist, chairman of the lunacy (special) committee and of the medico-political committee of the British Medical Association, expressed his agreement with this statement. He would like to see in the House of Commons a Minister who would look after the health of the nation. On December 14 Dr. J. B. Spence, medical superintendent of the Staffordshire County Asylum, stated that he favoured the amalgamation of the offices of Commissioner and Lord

Chancellor's Visitor. He would like to see all legally recognised insane and imbecile institutions of the country placed under the control of the Commissioners in Lunacy. On no account should any power at present exercised by the various county councils be relegated to the new board. Mr. P. P. Pennant, chairman of the Visiting Committee of the North Wales Counties Lunatic Asylum, said his committee felt that the usefulness of the Lunacy Commission would be extended by the addition of a number of members selected from the visiting commitee of, say, groups of counties. Mr. William Hodgson, chairman of the County Asylum, Chester, criticised the Commissioners with regard to their attitude towards local authorities in the matter of the erection of buildings.

Midwife Blamed.

An inquest was held at Rhymney on December 20th, when the circumstances attending the death of Miss Edith Frances Lloyd, of Rhymney, resulted in Mrs. Thomas, a midwife, being severely censured.

The evidence was that the deceased was a single woman, and that she gave birth to a still-born child on the 8th ult. The mother said she did not send for a midwife until an hour and a half before the child was born. A doctor was sent for in the evening, for witness did not think the child would be born till January.

The Coroner: You are a bigger fool than you look. The Coroner also questioned the deceased's sister on the same points.

Dr. D. Ll. Thomas said that when he saw the patient she was barely conscious. The *post-mortem* revealed that the bladder was injured. The immediate cause of death was blood-poisoning by urine. The injury to the bladder was, in his opinion, caused by pressure on the bladder during confinement. A midwife who knew her ordinary duty would be expected to know of such a state of things and how to deal with it.

Mrs. Margaret Thomas said she had been a midwife for thirty years. The reason she was not registered was because she had been to the "States," and on coming back was not aware that she need be registered. She took charge of the case about seven o'clock in the morning, and left about half-past ten a.m., and the condition of the young woman then was very good. Deceased had been sick, but she did not take any notice of that because a good many people were sick and got over it.

The Coroner said the evidence of the midwife showed that she was an ignorant woman. She had confined hundreds of women, and brought their children into the world by luck, and not by skill. There was a moral blame attached to the mother and sister, but with regard to the midwife they had to consider whether she was not culpable.

A verdict of "Death by Misadventure" was returned. The Coroner said the jury had also added a rider, severely censuring Mrs. Thomas, the midwife, for her ignorance, and they had seriously considered whether they would not bring the case before another tribunal, as this ignorance of her duties directly led to the young woman's death. In doing this, however, they had not lost sight of the fact that she was called in late. The jury also considered that the mother and sister of the deceased had been guilty of a grave error of judgment in not sending for the midwife and doctor sooner.

Tuberculosis in Stirlingshire.

At a recent meeting of the Western District Committee of Stirling County Council yesterday, a subcommittee reported upon a scheme proposed by Dr. M'Vail, involving voluntary notification, the equipment of a laboratory, and the appointment of an assistant to the doctor to deal with tuberculosis. In the event of Dumbartonshire combining in working out the scheme, it could be carried out at an annual expenditure of £242, plus £100 for equipping a laboratory. This on a net valuation of £860,000 could be done at a rate of ½d. per £1, half on owner and half on occupant. The question of imported cases of tuberculosis was raised—cases of town consumptives going out into the country and taking lodgings. Several members thought the county should not be at any expense in their case. Ultimately it was agreed to adopt Dr. M'Vail's scheme, provided the other districts did likewise.

National Maternity Hospital, Dublin.

Last week the new wing attached to the National Maternity Hospital, Holles Street, Dublin, was opened by Archbishop Walsh. The ceremony attracted a large company. Archbishop Walsh, patron of the institution, presided. Dr. P. J. Barry, on behalf of the governors, mentioned that the outlay connected with the erection and equipment of the new wing would exceed £4,000, and the expenditure of so large a sum completely exhausted the resources of the institution. The governors felt it their duty to carry out these improvements, trusting to the generosity of the public to recognise the merits and claims of the hospital. It was further mentioned, as an additional proof of its merits, that 10,000 visits are annually paid by the nurses of the hospital to poor women at their own homes.

Archbishop Walsh then declared the new wing opened, and after some further speeches the meeting terminated.

PASS LIST.

London School of Tropical Medicine.

The following candidates have passed the examination held at the end of the twenty-second session of the School, December, 1906:—

Major S. A. Harriss, I.M.S., M.B., C.M. (Edin.), M.R.C.S., L.R.C.P., D.P.H. (Camb.), F. M. Suckling, M.B., Ch.M. (Sydney), P. H. Pereira, M.B. (Madras), M.R.C.S., L.R.C.P. (Colonial Service), W. B. Orme, M.R.C.S., L.R.C.P. (Colonial Service), and Major J. B. Smith, I.M.S., M.B., B.A., M.Ch. (R.U.I.), with distinction. O. Blumhe, M.D. (Havana), W. Cammack, M.D. (N.W. University, Chicago), Mrs. W. Cammack, M.A., M.D. (State Univ., Iowa), E. P. Caropoulos, M.D. (Athens), C. F. Fothergill, M.R.C.S., L.R.C.P., M.B., B.C. (Camb.), B.A., D. Giordano, M.D. (Rome), H. W. Gush, M.B., Ch.B. (Edin.) (Colonial Service), F. I. M. Jupe, L.S.A., M.A. (Cantab), (Colonial Service), E. J. Maxwell, B.A., M.B. B.C. (Camb.), M.R.C.S., L.R.C.P., H. B. G. Newham, M.R.C.S., L.R.C.P., D.P.H. (Camb.), H. McG. Newport, M.R.C.S., L.R.C.P. (Colonial Service), Capt. J. M. Phalen (U.S. Army), Ph.G. (N.W. Univ., Chicago), M.D. (Univ. of Illinois), Miguel Paz, M.D. (Guatemala), A. B. S. Powell, L.R.C.P. and S. (Edin.), (Colonial Service), C. C. Robinson. M.B. (Lond.), M.R.C.S., L.R.C.P. (Colonial Service), F. O. Stoehr, M.B. (Oxon), K. R. Tampi, B.A. (Madras), M.B., Ch.B. (Edin.), W. A. Trumper, M.R.C.S., L.R.C.P., A. W. Wilson, M.D., B.C. (Camb.) (Colonial Service), and W. W. Woolliscroft, M.R.C.S., L.R.C.P.

Society of Apothecaries of London.

The following candidates passed in surgery:—R. L. H. Davy, G. B. Messenger, F. B. O'Dowd, W. F. Skinner, and S. H. Watton.

Medicine:—A. E. Blythman, R. L. H. Davy, Q. S. Keat, D. E. C. Pottinger, and W. F. Skinner.

Forensic Medicine:—R. L. H. Davy, D. E. C. Pottinger, W. F. Skinner, and W. W. Stacey.

Midwifery:—R. L. H. Davy and D. E. C. Pottinger.

The diploma of the society was granted to the following candidates, entitling them to practise medicine, surgery, and midwifery:—R. L. H. Davy and Q. S. Keat.

The Gresham Lectureship.—The appointment from the City of London held by the late Dr. Symes Thompson will be filled in February next. The necessary qualifications of applicants for the Gresham Lectureship on Physics have been altered to the following:—Candidates must have taken the degree of M.D. in some university of Great Britain or Ireland, or must be Fellows of the Royal College of Surgeons. The age limit has been withdrawn.

NOTICES TO CORRESPONDENTS, &c.

☞ **CORRESPONDENTS** requiring a reply in this column are particularly requested to make use of a *Distinctive Signature or Initial*, and to avoid the practice of signing themselves "Reader," "Subscriber," "Old Subscriber," &c. Much confusion will be spared by attention to this rule.

REPRINTS.—Reprints of articles appearing in this journal can be had at a reduced rate, providing authors give notice to the Publisher or Printer before the type has been distributed. This should be done when returning proofs.

CONTRIBUTORS are kindly requested to send their communications, if resident in England or the Colonies, to the Editor at the London office; if resident in Ireland, to the Dublin office, in order to save time in reforwarding from office to office. When sending subscriptions, the same rule applies as to office; these should be addressed to the Publisher.

ORIGINAL ARTICLES OR LETTERS intended for publication should be written on one side of the paper only, and must be authenticated with the name and address of the writer, not necessarily for publication but as evidence of identity.

SUBSCRIPTIONS.

SUBSCRIPTIONS may commence at any date, but the two volumes each year begin on January 1st and July 1st respectively. Terms per annum, 21s.; post free at home or abroad. Foreign subscriptions must be paid in advance.

DR. F. N.—Yes, the term "metallic ferment" is used. It signifies the metallic brines prepared after the method of Bredig by the action of an electric arc upon metallic salt solutions These brines have catalytic effects, and are sensitive to chemical and physical agents as ferments a e. They have been used for the treatment of disease by subcutaneous injection.

N. S.—Too much discretion cannot be exercised in dealing with patients of the unfortunate class. It is better not to make any effort oneself beyond writing to a good home and trying to enlist their interest. Several admirable institutions exist for the purpose, and we should advise you to write direct to the secretary of one of them.

LOCUM.—You may of course approach members of committee before a vacancy is actually declared, but it must rest with your judgment as to whether it is advisable to do so. If canvassing is not permitted . it is not unlikely that members may object to being button-holed at any stage in the proceedings, and you may do more harm than good. If the body is anything like a fair one, it will not allow solicitations of any kind, and we should, in a general way, advise you to act exactly as those candidates who have not your information.

F. J. K.—Surely the mere male is not competent to give advice on such a subject. As a matter of good taste we should certainly say "No," but people do not seem to regard the doings of the Suffragettes with any particular degree of aversion. Such a procession as you describe might break the flinty hearts of the President and Fellows, but we "hae our doots." We do not know any police-station in the immediate vicinity.

LESTER.—The Nobel Prize in Medicine for this year was divided between Professor Camillo Golgi, of Italy, and Professor Santiago Ramon y Cajal, of Madrid. The amounts received by each were over £3,500. The announcement appeared in the usual journals.

AN IMPOSTOR

A CORRESPONDENT asks us to warn our readers against a German, speaking excellent English, who seems to be making a point of calling on medical men for pecuniary assistance under the pretence that his wife's maiden name is the same as that of the individual called upon, to whom he says she is remotely related.

MR. E. J. R. OLIVER'S letter is unavoidably held over for want of space.

THE MOST POPULOUS CITIES OF THE WORLD.

THE official returns of the great cities from which the Registrar General receives statistics, excluding of course such as the Chinese, whence no enumeration comes to hand, are as follows:—London (not including suburbs), 4,684,794; New York, 3,948,191; Paris, 2,660,559; Berlin, 2,035.815; Chicago, 1,932.315; Vienna, 1,897,630; Philadelphia, 1,438,318; St. Petersburg, 1,248,122; Moscow, 1,092,360; Rio de Janeiro, 850,000; Calcutta 847,796; Buda-Pesth, 836,267; Glasgow, 809,986; Bombay, 776,006; Hamburg, 772.852; Liverpool, 730,143; Manchester, 631,185; Boston, 617,950; Birmingham, 542,958; Amsterdam, 554,240; Madras, 509,346; Brussels, 586,936; Rome, 514,930; Munich, 528,000; Copenhagen, 426,000.

MR. A. DINGWALL K. is thanked for his appreciative letter.

DR. ERNEST J.—Your communication is marked for early insertion.

M. O. H.—The question of "return" cases of scarlet fever and other infectious diseases has been fully dealt with in a series of original papers published in THE MEDICAL PRESS AND CIRCULAR in 1904. Whatever the general tendency of notification and isolation may be in the long run with regard to the two maladies mentioned, it certainly has not so far reduced the incidence of the disease. Mortality, however, has fallen considerably in both instances.

Meetings of the Societies, Lectures, &c.

WEDNESDAY, JANUARY 2nd.

OBSTETRICAL SOCIETY OF LONDON (20 Hanover Square, W.).—8 p.m.: A Specimen will be shown by Dr. A. Routh. Papers:—Dr. A. Donald: Chronic Septic Infection of the Uterus and its Appendages. Dr. W. F. Shaw: The Pathology of Chronic Metritis.

THURSDAY, JANUARY 3rd.

NORTH-EAST LONDON CLINICAL SOCIETY (Tottenham Hospital, N.).—4 p.m.: Clinical Cases.

ST. JOHN'S HOSPITAL FOR DISEASES OF THE SKIN (Leicester Square, W.C.).—6 p.m.: Chesterfield Lecture:—Dr. M. Dockrell: Bullous and Vesicular Eruptions: V., Herpes; VI., Zoster; VII., Dermatitis Herpetiformis.

FRIDAY, JANUARY 4th.

WEST LONDON MEDICO-CHIRURGICAL SOCIETY.—Clinical Meeting.

Vacancies.

Edinburgh School Board.—Medical Officer. Salary £400 per annum Applications to G. W. Alexander, Clerk, School Board Offices Edinburgh.

King Edward VII. Sanatorium, Midhurst, Sussex.—Pathologist. Salary £250 per annum, with board, lodging, and attendance. Applications to the Hon. Secretary, 19 Devonshire Street, Portland Place, W.

South Devon and East Cornwall Hospital, Plymouth.—House Surgeon. Salary £100 per annum, with board, residence, and washing. Applications to P. J. Langdon, Secretary.

Down District Asylum, Downpatrick. — Junior Assistant Medical Officer. Salary £130 per annum, with board, residence, and laundry. Applications to M. J. Nolan, Resident Medical Superintendent. (See advt.)

Newport Borough Asylum, Caerleon, Mon.—Assistant Medical Officer. Salary £150 per annum, with board, apartments, and attendance. Applications to the Medical Superintendent.

Carmarthen, Cardigan, and Pembroke Joint Counties Lunatic Asylum, Carmarthen —Junior Assistant Medical Officer. Salary £150 per annum, with furnished rooms, board, washing, and attendance. Applications to W. Morgan Griffiths, Clerk to the Asylum Visitors, Carmarthen.

Royal South Hants and Southampton Hospital.—House Physician. Salary £100 per annum, with rooms, board, and washing. Applications to T. A. Fisher Hall, Secretary.

Royal National Hospital for Consumption, Ventnor.—Senior Resident Medical Officer. Salary £200 per annum, with board and lodging. Applications to the Secretary, 34 Craven Street, Charing Cross, London.

Appointments.

DUNLOP, J. B., M.B., B.C.Cantab., Assistant Physician to the Bradford Royal Infirmary.

FORTY, A. ALAN, L.D.S.Eng., Honorary Assistant Dental Surgeon to the Leeds Public Dispensary.

JOHNSON, G. JAMESON, M.B.R.U.I., F.R.C.S.Irel., University Examiner in Clinical Surgery, Dublin University.

LITHGOW, J. D., M.B., C.M.Edin., F.R.C.S.Edin., Assistant Surgeon to the Ear and Throat Department of the Royal Infirmary, Edinburgh.

MILES, G. L. N., L.R.C.P. and S.Irel., Certifying Surgeon under the Factory and Workshop Act for the Farnham District of the county of Surrey.

PURVES, W., M.B., B.S.Edin., Certifying Surgeon under the Factory and Workshop Act for the Milnthorpe District of the county of Westmorland.

ST. JOHN, W. ST. A., M.R.C.S., L.R.C.P.Lond., Honorary Anæsthetist to the Derbyshire Royal Infirmary.

THOMPSON, THEODORE, M.D.Cantab., M.R.C.P., F.R.C.S., Physician to the Poplar Hospital for Accidents.

TURNBULL, Miss J. H., M.D., B.S.Lond., Surgical Registrar to the Royal Free Hospital.

TURNER, Major R. G., I.M.S., Clinical Assistant to the Chelsea Hospital for Women.

Births.

BALLANCE.—On Dec. 27th, at 4 Royal Terrace, Weston-super-Mare, the wife of H. Stanley Ballance, M.D., B.S., of a son.

FERNANDES.—On Dec. 24th, at Smallburgh Place, near Norwich, the wife of Ramsden W. L. Fernandes, M.B., C.M., of a daughter.

GREENWOOD.—On Dec. 24th, at Sowood House, Ossett, Yorks, the wife of William Greenwood, M.R.C.S., L.R.C.P., of a daughter.

SMARTT. On Dec. 27th, at Bowmere Cottage, Tarporley, Cheshire, the wife of Walter Smartt, F.R.C.S.I., of a son.

Marriage.

CARTER—SAVERY.—On Dec. 22nd, at All Saints' Church, Ealing, Charles, younger son of the late William Carter, of Coventry, to Ruth Key, youngest daughter of the late John Charles Savery, M.R.C.S., L.S.A., of Hastings.

Deaths.

FOWLER.—On Dec. 19th, at Overstone, Northants, the widow of William Fowler, M.D., of Altofts, Yorks, and second daughter of the late Thomas William Elford Morant, aged 79.

GIBBS.—On Dec. 27th, at 5 Riggindale Road, Streatham, Surgeon-Major John G. Gibbs, aged 80.

HART-SMITH.—On Dec. 28th, at 21 Adelaide Road, Brockley, S.E., John Morshead, son of Dr. Humphry Morshead and Julia Hart-Smith, aged two months.

MORISON.—On Dec. 25th, at Springfield, West Hartlepool, Lizzie, second daughter of the late Captain Morison, Broadhempston, Devon, and beloved wife of Fred H. Morison, M.D.

NETHERCLIFT.—On Dec. 28th, at Thornhurst, Bournemouth, William Henry Netherclift, F.R.C.S., J.P., of Canterbury.

NORTON.—On Dec. 26th, at 6 Salford Road, Fanny Sophia, widow of the late Robert Norton, M.D., of Bayswater, aged 84.

SCUDAMORE.—On Dec. 26th, Annie Bell Scudamore, wife of the Rev. J. C. Scudamore, Rector of Ditchingham, and daughter of C. F. George, M.R.C.S., of Kirton-in-Lindsey.

TOLLER.—On Dec. 20th, at The Zephyrs, Scarborough, Ebenezer Toller, M.R.C.S., formerly Medical Superintendent of St. Luke's Hospital, London, and late Medical Superintendent of the Gloucester County Asylum, in his 77th year.

WADE.—On Dec. 26th, in London, Surgeon-General F. W. Wade, in his 78th year.

THE MEDICAL PRESS AND CIRCULAR.

"SALUS POPULI SUPREMA LEX."

VOL. CXXXIV. WEDNESDAY, JANUARY 9, 1907. No. 2

NOTES AND COMMENTS.

Unpaid Bills.

IN illustration of what we said last week about the virtuous indignation of newspapers against medical men who are put upon or actually cheated by careless or unscrupulous people, we may mention a striking instance which has come to notice. An inquest was held at Liverpool at the end of last month on a woman who died in a confinement. It appears that she was attended by an unregistered midwife, and that when things were found to be going wrong, the latter sent for an unregistered practitioner to help her. This person recognised that still further help was necessary, and sent for a local medical man, who replied that he could not meet him in consultation, but that he would attend if the unregistered practitioner retired. This having been accomplished, Dr. Billiard, the medical practitioner, went to the house, although he had an unpaid account against the patient, and finding the woman seriously ill he called in a colleague. Together they decided that the case was one for hospital treatment, and Dr. Billiard himself promptly went to the hospital and ordered them to send the ambulance at once. Through some misunderstanding this was not done, and eventually another practitioner, to whom money was also owing, was called in. By this time the child was partly born, and when it was delivered it was found to be dead. The mother, too, died shortly afterwards from rupture of the uterus.

And Gratitude.

Now what inferences do these facts obviously suggest? In the first place, surely, that people who run up accounts with medical practitioners and do not pay them should consider themselves fortunate indeed that in emergency these practitioners will still come to their aid; and in the second that the practice of unregistered persons, be they medical men or midwives, constitutes a grave abuse, and that people who employ them must take the consequences of their actions. And, thirdly, on reading the reports, we cannot fail to be struck with the care exercised by Dr. Billiard in the conduct of the case and his energy in going himself to secure the ambulance. No satisfactory reason seems to be forthcoming as to why it was not sent, and this appears to be not the least unfortunate part of the case. What actually happened, however, was that Dr. Billiard was severely censured by the coroner's jury for leaving the woman, and a prominent local paper published a leader dealing with the subject and expressing a hope that "this experience of the doctor will be wholesome in its effect"! If this is the way that medical men are to be treated by the public, it will be necessary seriously to revise the attitude of the profession to the community.

A Kindly Act.

IT is a comfort to turn from a case of such ingratitude to one in which a medical man was specially commended by a jury for his kindness. On Christmas Day, Dr. Conrad Basan was called to see the child of a street hawker in the East End of London and discovered that it was already dead. The mother said that she had been feeding it with a patent food and that it had been "wasting away." When she woke in the morning she found it dead. Dr. Basan saw that the parents were in a state of dire poverty—they had no food, no fire, and very little bedding—so he gave them five shillings and some fare appropriate to the season. At the *post-mortem*, the child's body was seen to be much emaciated, and Dr. Basan gave it as his opinion that it had died from exhaustion from want of proper and sufficient food. The jury, having found that the child died from "natural causes"—(Are starvation and improper feeding considered "natural" in East London?)—expressed a strong opinion on the doctor's kindness of heart. It is pleasant to have such testimonies to counterbalance the others.

Wrexham Guardians and Superfluous Luxuries.

THE Wrexham Guardians have covered themselves with glory. It seems that they recently built an operating theatre in connection with the workhouse infirmary, and when its erection was complete the Buildings Committee found the lighting had been so badly planned that it was necessary to build a special window at a cost of £30 before the theatre could be used. One would have thought that having thus been convicted of their own short-sightedness, the Guardians would have been only too eager to remedy any other defects that had been overlooked, but such was not the case. Their medical officer pointed out last month that no water-supply was laid on to the theatre, and that such a supply was not only essential for surgical reasons, but would cost only about £7 10s. Such a luxury, however, the Committee could not allow, and when their report came before the full Board the chairman said if they went on in this way they would never know where to stop. A medical member of the Board pointed out that it was practically useless to build a theatre without a water-supply, but his advice was contemptuously rejected by the "intellectuals," who decided to leave the theatre waterless. We should suggest that a matter of this kind involving the most vital question in connection with the efficacy of surgical treatment might with propriety be brought to the notice of the Local Government Board, which, fortunately, have mandatory powers in questions of public health. Recalling a *quondam* crusade of Mr. Stead's, we cannot help wondering what would happen if "Lister came to Wrexham."

Majolica Painting and Lead Poisoning. MEDICAL men have an important duty to perform in the education of people on questions of public health, and there are few departments in which it can be exercised more beneficently than in teaching the effects of dangerous trades. Many of these trades are created and kept alive by a demand for luxuries and ornaments, and if the demand ceased the trade would follow suit. For instance, if leadless glaze for pottery-ware were demanded by people, and lead glazes refused, plumbism among potters would be largely reduced. At Hanley recently an inquest was held on the body of a woman, aged 38, who died of chronic lead poisoning which she appears to have contracted in her occupation as a paintress of majolica ware. Now the world would be no little less happy if it were without majolica ware, and it seems likely that some miserable deaths might be prevented. The conclusion is obvious. It is hardly possible to believe that people who cry out loudly against wearing birds' feathers in ladies' hats, would not recognise the infinitely greater inhumanity of adorning their mantel-shelves with an absolutely unnecessary class of ornament manufactured at a cost to human life.

Medical Journalism and the Lay Press. AN important letter appears in the last issue of one of our weekly contemporaries from the pen of Dr. J. Hopkins Walters, of Reading, in which the writer refers to a matter of considerable importance to the profession from the point of view of medical ethics. It appears from his letter that a well-known monthly medical journal is in the habit of sending to the lay press advance sheets of its forthcoming numbers, and this Dr. Walters contends is a direct invitation to the lay press to publish extracts from them. The result of this practice was very apparent in the case of the last number of the journal in question, large extracts from which with sensational headings and the names of the authors attached, appeared in the daily press. Dr. Walters has addressed a letter to the editor of the medical journal in question, in the course of which he writes:—"Since it is very properly considered unprofessional for a medical man to publish communications in other than professional journals, I cannot understand why the editors of professional papers should consider themselves free from the same obligation." The letter is a timely one, and we trust that it will have the desired effect. If it does not, it will become necessary for would-be writers for the journal in question to consider whether by their contributions they are not involuntarily infringing a very direct precept of medical ethics. Sensationalism in medical journalism is as unsuitable as it is in the case of our venerable contemporary, the *Times*, and is certain in the end to meet with the censure of the medical profession.

LEADING ARTICLE.

A ROYAL COMMISSION ON QUACKERY.

The present Government, under the leadership of Sir Henry Campbell-Bannerman, appears to be directing its main energies towards social reform. That being the case, we venture to draw the attention of the Cabinet to a canker that is eating deep into the vitals of the nation, namely, that of quack medicines and quackery. The British legislature, on the one hand, has ensured that legitimate medical practitioners shall be well educated and duly qualified for the practice of their profession. On the other hand, they have made no provision for the exclusion either of professionally ignorant and untrained charlatans of all kinds. More than that, by the action of the patent medicine stamp, Government raises a paltry revenue and thereby sanctions the sale of remedies that are in many cases shameless and wicked frauds. There is no need here to enter into the story of the harm that is done. The tale is hackneyed enough. Every medical man knows of lives that have been cast away by the use of nostrums, of infants that have been killed by "soothing syrups" and "teething powders," of limbs distorted by bonesetters, of sufferers from malignant disease fleeced, deluded, and condemned to die in untold agony by "cancer curers." Every day of the week every general newspaper records instances of lives thrown away through one or other of these nefarious agencies. Yet, as we have often pointed out, the very newspapers that contain these damning reports publish the advertisements by means of which rogues and charlatans are enabled to secure their victims. As if our own insular roguery were not enough, the country is being constantly flooded with American frauds of a similar nature. Elsewhere we publish the report of an inquest held by the City of London Coroner upon a labourer who had spent three guineas upon an inhaler from Ohio, U.S.A. The poor man died of consumption, and was induced to pay five shillings an ounce for fluid to be used in the appliance. Probably the total value of inhaler and fluid would be a few pence, and their value in phthisis absolutely *nil*, yet the Government sanctions this traffic with an official stamp. The whole trade in nostrums and illegitimate medical practice is monstrous. In Bond Street, London, an unqualified woman has recently had the impudence to put a large brass plate on each side of a doorway with the words "skin specialist" after her name. Every large town in the United Kingdom, however, can produce its particular crop of parasites of society in the shape of cancer curers, bonesetters, rupture healers, electrical quacks, and so on. This is an Augean stable that should forthwith be cleansed by the State. The evil has been too long with us. It is wrapped up in various vested interests, among which various wealthy patent medicine companies and powerful journals many be mentioned. In Parliament itself, as a rule, there are members interested as shareholders in and directors of patent medicine companies whose claims are an outrage upon educated common-sense and reason. Not long ago we inspected the list of shareholders of a notorious "cure" for kidney diseases—its claims so outrageously false as to touch the fringe of fraudulency—and there we were surprised and pained to find the names of various prominent members of the House of Commons. What is wanted is the education of the moral and intellectual sense of the nation as to the harm that is being wrought on all hands by quacks and quackery. The best means of arriving at the facts of the case, in our opinion, is by the institution of a Royal Commission. The terms of reference might be made to include the extent of irregular medical practice, the harm done thereby, and the profits obtained therefrom, with evidence of inquests, prosecutions, and so on. The claims of patent medicine vendors might be similarly investigated by the Commissioners. The extent and nature of the trade and its relation to the public, the medical profession, and the newspaper and advertising agents would demand careful investigation. In this way the road would be paved to the ultimate removal of a traffic that is degrading to our boasted civilisation and to the latter-day sense of responsibility to our fellow citizens that marks modern altruistic government. To such a Commission as we have suggested the editor of The Medical Press and Circular would engage to bring a mass of evidence that would thrill the heart and conscience of the nation. We respectfully urge upon the Premier of this great nation that in defence of the bodily welfare of His Majesty's subjects he should take steps to protect them from the harmful practices of quacks and patent medicine vendors. As a first practical step in that direction we ask Sir Henry Campbell-Bannerman to institute an enquiry by Royal Commission into the existence and extent of this deplorable traffic.

CURRENT TOPICS.

A Bonesetter's Challenge.

In our issue for January 2nd, we criticised the methods of Mr. Barker, a bonesetter who recently issued a challenge to the President of the Royal College of Surgeons of England to a sort of public duel. We insisted upon the impossibility of a meeting on any common ground of a qualified medical man and an irregular and, from our point of view, technically untrained and ignorant person. A surgeon acts on principles and rules that are open to his fellows, and for that matter to the whole world. Mr. Barker, on the other hand, claims to achieve results unobtainable by the medical profession with all its accumulated wealth of knowledge and experience and its whole-hearted search after truth. Mr. Barker publishes long-winded statements of the wonders he can perform, and refers therein vaguely to some mysterious personal skill or knowledge, but he furnishes no details, and apparently trusts to his own native intuition for diagnosis, pathology and results. This sort of haphazard observation may be good enough for bonesetting, but is hardly likely to be countenanced by the exact science of surgery. As might have been anticipated, in answer to our strictures Mr. Barker has issued a challenge to the Medical Press and Circular It is impossible to avoid admiring his persistence, for by this time he must know that as the cartel cannot be accepted, to issue a fresh one is mere swashbuckler bravado. However, it is only fair that he should have his answer recorded. He wishes to pit his skill against that of qualified surgery in the treatment of six selected cases of talipes valgus, not congenital, and six of dislocated semilunar cartilage of the knee. As to the former condition, it is well within the command of any skilled surgeon, in fact, some cases can be completely cured by intelligent nursery manipulation. As to the latter, any one with a competent knowledge of surgery can restore a semilunar cartilage by manipulation. The difficulty is to keep it in position. As a rule, the dislocation recurs again and again, and in obstinate cases the only effectual remedy is to "moor" the cartilage, or else remove it altogether. It is seldom that the single replacement of a cartilage that has frequently slipped will be followed by an immediate and permanent cure. Mr. Barker sends us a letter from a well-known football player, asserting that he was cured of an obstinate knee by a single manipulation and that he has sent lots of his athletic friends with similar results. The letter, we find, was written two months after the "one and only" treatment, a period that renders the case worthless as evidence. The matter ends here, as it began, with Mr. Barker's *ipse dixit*. So far as we are concerned, he is welcome to any advertisement that may be gathered from his numerous challenges.

Hospital Abuse and the Profession in London.

Two significant meetings have been held during the past few weeks dealing with the subject of hospital abuse—the meeting of the Hospital Officers' Association on December 21st, and that of the Westminster Division of the British Medical Association on December 17th. The instructive element at the first-named meeting was the speech of Mr. Sydney Holland, denying *in toto* that any hospital abuse exists. This may be taken as the typical attitude adopted nowadays by the members of the governing boards of the great hospitals. The members of the medical staffs are in a slightly different case. Unable to deny the existence of the evil, they avoid the question altogether, or treat it as one of small importance. The tone of the Westminster meeting, however, and that of other meetings of practitioners recently held, show that this Gallio-like attitude will not be much longer tolerated The patience of the general practitioner is nearly exhausted. He is robbed in the house of his friends. And not only he, but the benevolent public, is being defrauded through the *laissez-faire* carelessness of hospital authorities. If certain of the threats made in speech and print by general practitioners recently be carried into effect, and hospital finances suffer, it is the hospital authorities, and they alone, who will be to blame.

Drainage by Suction.

Drainage by water has been so universally adopted throughout the kingdom that we are inclined to forget several of the disadvantages to which it is subject. A rich water supply, and a sufficient fall of ground are the first necessities. The system is, moreover, wasteful, and not unlikely to cause contamination of drinking water by percolation through imperfect pipes. It is of importance to remember, therefore, that there are alternatives, and the trial given to one of these at Stansted, Essex, is instructive. For the past four years, the system known as the "Liernur method" has been at work as an experiment at Stansted, and the local authority is so satisfied with the result that it has now obtained permission from the Local Government Board to purchase the works outright. The principle of the system is simply suction, all sewage material being drawn to a common storage tank. It may, in fact, be regarded as a gigantic "vacuum cleaner." It is claimed for the Liernur system that it is inexpensive and efficient, and it is obvious that it has applicabilities in places where there are objections to the water system Thus, Trouville has been for many years drained in this way. There, as in other seaside places, the discharge of sewage into the sea is distinctly unpleasant, in suggestion if not in fact, and it is likely that in such situations the Liernur system will before long be widely adopted.

London Ambulance Service.

IT is nothing short of a disgrace that a city of the immense size and importance of London should be without any organised method of dealing with street accidents, or means for transportation of the sick poor, and the fact that after years of agitation no definite plan of action has been devised speaks badly for the practical genius which is supposed to characterise the English. Since the matter has been mooted and brought before various responsible authorities, steps and countersteps have been taken, and now, after the County Council have been wrestling with the subject for more than a year, owing to political difficulties it has been necessary to place the matter in the hands of the Home Secretary. Mr. Gladstone has now appointed a Departmental Committee to enquire into what are somewhat facetiously called the "existing facilities" for dealing with street accidents and cases of sudden illness in the Metropolis, and these gentlemen may be urged to make all due speed in a matter that has waited far too long. The London County Council scheme for which they recently sought Parliamentary powers was modest enough. Its capital outlay was only £13,000, and £9,600 a year was all that was needed for maintenance. Considering that of street accidents alone there are some twelve thousand a year, these figures cannot be considered excessive. The City Corporation, which is in the happy position of being able to do much more what it likes with its money than the County Council, have already one motor-waggon at work and will soon have others. As the question for London has now been referred to the Home Office, probably the ambulance service will be associated with the police force, and one would suppose that little enough ingenuity would be needed to place the service on permanently satisfactory footing. But the delay that has taken place is a scandal which only a long-suffering and law-abiding people would have put up with.

Dr. Doyen's Cancer Serum.

One-half the mischief done by the advocates of this, that, or the other so-called "cure" for cancer is their pernicious habit of premature publication. It is clear that any surgeon who claimed success for his cases within a year or two of operation would become the laughing-stock of the scientific world. Why should the physician who uses a serum or other drug treatment be entitled to reject the wholesome restraint adopted by the surgeon by noising abroad his tentative theories and crude experiments? Perhaps the greatest offender in Europe is Dr. Doyen, of Paris, who persists in claiming success for his cancer serum, in spite of the fact that it has been fully investigated and discredited by Metchnikoff and others, appointed by the French Academy of Medicine. At one time it was generally believed that the late Countess of Clancarty had been cured by him. As a matter of fact, we believe that in the year 1904 the lady in question underwent the operation of hysterectomy for malignant mischief and placed herself later under Doyen's cancer serum treatment. Recently the disease returned, and a second operation was performed, but without success. Under similar circumstances any reputable and responsible surgeon would not have claimed the case as a success, but, as already pointed out, certain physicians appear to override tradition and etiquette when dealing with this terrible malady. No better illustration of the fallacy of their faith could be imagined than the death of the above-mentioned unfortunate patient.

A Record Death Rate.

The fourteenth annual report of Sir Shirley Murphy, medical officer of the Administrative

County of London, for the year 1905, shows a saving of 19,584 lives compared with the decennium 1891-1900. The death rate for 1905 was 15.1 per 1,000 living. These figures are the lowest yet recorded in the steady fall that has taken place since deaths were first systematically recorded. In the decennium 1841-50 the rate was 24.8. The record figure of 15.1 compares favourably with that of Paris 17.4, Berlin 17.2, Vienna 19.3, New York 18.3, Rome 20.6, and St. Petersburg 25.0 for the same period. In London itself there were the usual striking contrasts in the returns from different districts. Hampstead maintained its reputation as the healthiest suburb by the exceedingly good rate of 10.5, while Lewisham comes second with 12.2. Shoreditch, on the other hand, has the unenviable distinction of finishing the list with a death rate of 20.7. In many unhealthy slum sub-districts the rate has naturally been much higher. The birth rate, which has shown a further diminution, stands at 27.1 for the year 1905. On the whole the report is a most highly satisfactory and encouraging document. The fair ideal would be to bring the whole figure for London to the 10.5 now attained by Hampstead, although the latter is doubtless capable of improvement, chiefly, perhaps, by the restriction of infectious diseases.

Night Calls in Vienna.

The city of Vienna is taking practically in hand the question of calling medical men up at night. In Continental towns the conditions of life are considerably different from what they are in this country, for a medical man going out at night has to pay fees to the porter of the building in which he lives, both on going out and on returning, besides also frequently paying the corresponding functionary in the patient's building. As the practitioner has often and often found himself unpaid by the patient, he is rather chary about leaving his bed and incurring expense without knowing something of the people who send for him. An Ambulance Society have therefore taken the matter up, and they propose to keep at police-stations a list of medical men who are willing to respond to casual calls at night, whilst the society are demanding that the municipality shall guarantee the fees ot all practitioners called up through this agency. This step is a really practical one, and meets the arguments on both sides. Need we say that we wish our colleagues every success in their battle against ingratitude and imposture ?

PERSONAL.

Sir Alfred Jones, Chairman of the Liverpool School of Tropical Medicine, has sent the following telegram to the Emperor of Germany:—"As President of the Liverpool School of Tropical Medicine, I desire to congratulate your Majesty on recent valuable work done by Professor Koch in confirmation of the discovery made by the Liverpool School of Tropical Medicine of a possible remedy for sleeping sickness."

A complimentary dinner was given to Dr. Norman Walker last week in Edinburgh to celebrate his election as Direct Representative for Scotland on the General Medical Council.

Dr. Jas. Burnet, senior clinical tutor in the medical wards of the Edinburgh Royal Infirmary, has been officially recognised as a Lecturer on Materia Medica and Pharmacy.

Dr. R. R. MacNicol, of Taynuilt, and Dr. Lachlan Grant, of Ballachulish, have been placed on the Commission of Peace for the County of Argyll.

On December 29th, in the Drill Hall, East Linton, a public presentation was made to Dr. James Gordon, on his retirement after close upon forty years' professional practice in the county.

Mr. Andrew Carnegie has offered to place a fund sufficient to produce £500 a year at the disposal of Paris University for a Natural Philosophy Scholarship in honour of the Curies.

Mr. W. Bryce Orme, M.R.C.S.Eng., has received the Royal Licence to wear the insignia of the Fourth Class of the Imperial Ottoman Order of the Medjedieh, recently conferred upon him by the Khedive of Egypt.

The annual meeting of the Incorporated Society of Medical Officers of Health will be held on January 11th at Bristol, when Dr. D. S. Davies will deliver the presidential address.

Sir Rubert Boyce has sailed from Liverpool on a voyage to the Canary Islands.

We understand that Professor Rose, of King's College, has recovered from his recent illness, and will shortly resume his professional duties.

Mr. W. H. Brown, who has been honorary surgeon to the Leeds General Infirmary for sixteen years, has had to resign that position owing to ill-health.

Lieutenant T. J. Wright, R.A.M.C., has been appointed a specialist for the prevention of diseases in India.

Dr. D. S. Davies, Medical Officer of Health for Bristol, will give the Presidential Address to the Incorporated Society of Medical Officers of Health on January 11th.

Dr. J. H. Croudace has been appointed a Justice of the Peace for the Borough of Stafford.

Dr. T. W. Conway has been appointed as assistant to the master at the Coombe Hospital, Dublin, in succession to Dr. M. J. Gibson, whose term of appointment has expired.

Dr. H. M. Thompson was made the recipient of a handsome travelling and dressing-bag on leaving Mexborough to take up work at Grimsthorpe.

Dr. R. B. Sellers, on resigning his post as Senior Surgeon to the Rochdale Infirmary, has been elected Consulting Surgeon. A complimentary resolution was passed by the Board on the occasion of the election.

Surgeon-Captains A. B. Lyon, T. P. S. Ward, and R. T. Ferguson have been appointed Surgeon-Majors, and Surgeon-Lieutenant H. Stallard, Surgeon-Captain, in the Army Reserve of Officers.

The will of the late Dr. David Jones, aged 72, of Hampstead, has been proved at £16,008.

Dr. Robert Lancelot Sparrow, of Oldham, has been enrolled as a magistrate for the County Palatine of Lancashire.

A CLINICAL LECTURE

ON

CASEOUS PNEUMONIA.

By PROF. DEBOVE, M.D.,

Doyen of the Faculty of Medicine of Paris, Physician to the Beaujon Hospital.

[SPECIALLY REPORTED FOR THIS JOURNAL.]

THE patient whose case I propose to discuss to-day is suffering, as you are aware, from caseous pneumonia. His history is of interest in that it raises several clinical and theoretical problems, some of which are *à l'ordre du jour*.

He is æt. 30, and is by profession a bookkeeper. He dates back his illness to three months ago, *i.e.*, to the early part of January. At that date he caught a slight cold, which did not oblige him to cease work, but on January 28th he suddenly got worse, the cough became more troublesome, and he was seized with a violent shiver and pain in the right side without any expectoration. He tried to go on with his work, and only took to his bed three days before his admission to hospital, namely, January 26th. When first seen the constitutional symptoms—prostration and fever—attracted most attention, and the house physician who examined him diagnosed typhoid fever and prescribed cold baths.

This was certainly an error of diagnosis—a very excusable error, and one which I should certainly have committed had I made the examination at that date, for the high temperature, with its morning remissions, the general condition, the absence of any localisation, and the existence of a fairly long period of invasion preceding the onset of serious symptoms, seemed to suggest this diagnosis.

On February 28th, the pain in the side became very severe, and attention was again directed to the right side of the chest. Dulness was found over the right base with blowing expiration and egophony. The cough was dry, harassing and without expectoration. On the supposition that he was suffering from pleurisy, two exploratory punctures were made without result, and from that moment the diagnosis of tuberculous pneumonia was established.

You will have noticed that I throw the blame of the errors of diagnosis on my house physician, who looked upon the case as an ordinary one, and only drew my attention to it when doubts arose in his mind. Had I observed the patient from the beginning, it is highly probable that, misled by the onset of the fever and by the general condition, I should have diagnosed typhoid fever, and that later, in presence of the local signs in the chest, I should have diagnosed pleurisy, arriving at the diagnosis of caseous pneumonia as a last resort.

I recall these details just to show you that the consultant who is called in at a late stage of the disease, at a time when it is fully developed, ought to be lenient towards errors of diagnosis on the part of a colleague. As a matter of fact, I was not called upon to correct any mistake, for the diagnosis had been made when my attention was called to the patient. This was the state in which I found him :—

Pale, much emaciated, he was so weak as to be unable to sit up without assistance, and he spoke in a low jerky voice. His temperature averaged 100.5° in the morning and 103° F. at night. He had profuse night sweats. Dyspnœa was very marked and was increased by the slightest movement. The expectoration was mucous, and bacteriological examination, several times repeated, failed to show any tubercle bacilli.

The dyspnœa, the expectoration, the pain in the side, and the history of the previous symptoms naturally directed my attention to the chest, and this is what I found : The right side of the chest was slightly retracted, or, at any rate, was less developed than the left side. It may occur to you that this retraction might be due to a former pleurisy, which has undergone absorption, but if so the absorption must have been very complete, for no trace of it remains now.

The dulness is well-marked over the lower half of the right lung, and is absolute in the axillary line ; percussion under the clavicle on the right side gives exaggerated resonance. I may tell you in advance that this is probably due to the pushing up of the healthy part of the lung by the caseous mass that occupies its lower half. On auscultation we find that the vesicular murmur has disappeared over the greater part of the lung ; it can be heard only at the apex, and there very imperfectly, because it is masked by the blowing sound which is audible all over the right side but most marked in the regions where the dulness is most pronounced. This murmur originally presented the character of the pleuritic rub, then gradually became tubular; at the present time it may fairly be described as cavernous. Now that we are in possession of these stethoscopic data we are in a position to diagnose the local lesion.

It is not pleurisy, though the pain in the side, the dulness, the skodaic resonance, and the pseudo-cavernous signs might lead one to suppose so. The futile exploratory punctures show that clearly enough, but there is one sign in particular to which I desire to call your attention—a very important sign in this instance—namely, the persistance of vocal resonance, which, in certain parts, is, indeed, exaggerated. It appears that this was not the case at the beginning, thus complicating the diagnosis. What, then, can the lesion be ? It certainly cannot be a lobar pneumonia ; its duration alone proves that. Cancer of the lung might, it is true, give the same local signs, but the general symptoms and the course of the disease at once negative this diagnosis. We arrive, then, by exclusion, at the only alternative, namely, that it is a case of caseous tuberculous pneumonia.

I presume you are familiar with the anatomical lesions that characterise this form of tuberculosis. One or several lobes of the lung are converted into a solid cheese-like mass. The presence of this compact mass explains the dulness, the persistence of vocal fremitus, and the audibility of the breath sounds in the larger bronchi with the production of pseudo-cavernous signs. The tuberculous infection explains the fever, the sweats and the bad general condition.

We do not, however, get the characteristic expectoration of tuberculosis, but clinical experience teaches us that these caseous masses may remain solid for long periods of time, and it is only when the mass begins to break down that we get sputum of the usual kind containing bacilli.

The symptoms in general justify the conclusion that there is tuberculosis, for although we are not able to demonstrate its existence in the lung we have succeeded, with the assistance of our pathologist, in discovering bacilli in the patient's blood and urine.

We owe the ability to discover these bacilli in the blood to M. Jousset's inoscope. The clot is dissolved in a fluoropeptic fluid, the formula of which is known to you. This sets free the bacilli imprisoned in the fibrin, and their presence is readily demonstrable after centrifugalisation by the usual methods of staining. This procedure has been criticised on the ground that the tubercle bacilli may be confounded with acid-resisting saprophytes which present the same reactions to stains as the tubercle bacillus, but these pseudo-tubercle bacilli multiply rapidly in ordinary culture media. Now the bacilli isolated by M. Jousset's procedure did not multiply, and inoculation of guinea-pigs gave positive results.

The urine, scanty and of a dark colour, is intermittently albuminous. This albuminuria, which has never been very pronounced, disappears on some days only to reappear later. The maximum quantity has been 35 centigrammes to the litre. There is evidently a cyclical nephritis, for on each occasion granular casts have been seen. The most interesting feature, however, was the presence of tubercle bacilli, the bacillary crises coinciding with the albuminuric crises, a coincidence to which M. Jousset has directed attention in his monograph on "The Kidney and the Tubercle Bacillus." (a) These data are not based only on microscopical examination, which is often fallacious in urinary researches, but on the results of inoculation of guinea-pigs with centrifugalised urine.

Our patient, therefore, is both bacilluric and bacillæmic, and the blood and the urine have furnished us with information which we were unable to obtain from the expectoration.

You may ask whether bacilluria necessarily implies tuberculous nephritis. By no means! It is met with in tuberculous patients exempt from nephritis, or in whom at any rate the nephritis is so slight that no clinical evidence of its existence is obtainable.

Let us now enquire into the genesis of the pulmonary symptoms presented by our patient, and seek to ascertain their origin. It may be taken for granted that every tuberculous subject contracted his malady from some other subject similarly affected. There is no such thing as spontaneous generation in respect of tuberculosis. When and where, then, did he contract the disease? He tells us that he lost a sister from galloping consumption some ten years ago. Could he, at that date, have contracted the germs of the disease which has remained latent for that space of time? This is theoretically possible, but it is highly probable that his infection is much more recent. He is employed by a large insurance company, working with fourteen other employés in an office of comparatively small dimensions. Several of his colleagues, he says, coughed and expectorated on the floor, and one of them recently died of phthisis. It is therefore probable, though hardly demonstrable, that he caught the disease at his office.

But if the mode of infection is difficult to establish, it is even more difficult to explain why the disease has assumed this peculiar anatomical form—that of caseous pneumonia. With regard to the various forms which pulmonary tuberculosis may take, it is customary to assume that the choice is determined by the individual receptivity of the subject or the special virulence of the bacillus, and by skilfully juggling with these two factors we can easily satisfy those whose critical spirit is not too highly developed.

But when we are called upon to explain why the disease assumes a particular anatomical form, we are at a loss what to say. What explanation can be offered of this invasion of an entire lobe of the lung by lesions comparable with those of pneumococcal pneumonia? How can we admit this methodical, massive invasion of the pulmonary alveolæ throughout an area of the pulmonary apparatus which is both extensive and yet strictly limited. That is a mystery upon which I am unable to throw any light, and it is at least as difficult to explain as that of lobar pneumonia proper. It is not the same germ, it is true, but in each case we do not know either why the disease sets in suddenly or why it remains strictly circumscribed.

The task is in no wise facilitated if we assume that infection is propagated, not by the air passages but *via* the blood. Let me remind you that our patient's blood contains bacilli. Now for some time past the trend of opinion is in favour of alimentary infection obtaining admission by the intestine and being propagated by the blood.

Bacilli that pass in with the food enter the chyliferous ducts, for which no solution of continuity on the part of the intestinal mucosa is required, and are retained (in the child and young animal) in the mesenteric glands. Thence they migrate to the thoracic duct, and ultimately pass into the blood.

If this be the case, the occurrence of pulmonary tuberculosis is not so much due to bacilli mixed with inspired dust as to the special anatomical situation of the lung in the circulatory system and also to the minuteness of its capillaries which arrest the bacilli all the more readily. The microbes are evidently more easily absorbed by the chyle ducts than by the veins, for tuberculosis of the liver is extremely rare compared to its occurrence in the lungs.

All these problems are still under investigation, and have not yet been solved. However this may be, whether the bacillus arrives in the lung by the respiratory tract or by the veins, no explanation is afforded of the reason why one whole lobe of the lung is invaded independently of the rest of the pulmonary parenchyma. The bacillæmia may just as well be a consequence, as a cause, of the caseous pneumonia. In any event, we know that they are almost invariably associated, and this is in marked contrast with what we find in other forms of pulmonary tuberculosis. It would seem, says M. Jousset, that bacillæmia has more to do with the extent than with the severity of the lesions.

With regard to the prognosis, I can only say that it is of the gravest. With such a lesion death is inevitable, and the only point we might discuss would be its probable duration

The treatment is purely palliative, but should the temperature fall and the course of the disease become less rapid, it would be our duty to employ the methods of treatment applicable to chronic phthisis. In the present state of our knowledge that is the most we are justified in hoping.

NOTE.—*A Clinical Lecture by a well-known teacher appears in each number of this journal. The lecture for next week's issue will be by Dr. Robt. Alex. Fleming, F.R.C.P., Lecturer on the Principles and Practice of Medicine in the Edinburgh Medical School, Assistant Physician to the Edinburgh Royal Infirmary, the subject being "Optic Neuritis and Its Relationship to Intercranial Tumours."*

CLINICAL LECTURES FOR 1907.

In addition to the list of "Clinical Lectures" promised us during the current year, which we were privileged to publish in our last issue, we have since received the following :—

HY. GILBERT BARLING, M.B., B.S.Lond., F.R.C.S., Dean of the Faculty of Medicine, Professor of Surgery, and Ingleby Lecturer in Birmingham University.

G. W. SCOTT CARMICHAEL, M.B., C.M.Edin., F.R.C.S., Surgical Registrar to the Royal Infirmary, Edinburgh, Surgeon to the Royal Infirmary for Sick Children.

ARTHUR C. LATHAM, M.D.Oxon, F.R.C.P.Lond., Physician to and Lecturer on Medicine, St. George's Hospital, London, Asst. Physician to the Brompton Hospital for Consumption.

E. PERCY PATON, M.D.Lond., M.S., F.R.C.S.Eng., Dean of Westminster Hospital Medical School, Asst. Surgeon to and Lecturer on Surgical Pathology, Westminster Hospital.

(a) "Rein et Bacille de Koch," *Arch. de Med. Experimen.*, Oct. 1904 No. 5.

ORIGINAL PAPERS.

SOME NOTES ON EXAMINATIONS FOR LIFE ASSURANCE.

By R. SHINGLETON SMITH, M.D.Lond., F.R.C P.,
Consulting Physician to the Bristol Royal Infirmary and Emeritus Professor of Medicine, University College, Bristol.

It is commonly supposed that any qualified medical man is competent to undertake life insurance examinations, and many no doubt undertake them with little sense of the nature of their duty to the office by whom they are employed, often with no previous training, and with little knowledge of the problems which they may be called upon to solve. Of late, however, a tendency has been growing in favour of the idea that a life insurance examiner must be a universal specialist, and that no report can be considered complete unless the physical examination of the applicant has included the use of pretty well all the special methods of diagnosis known to the specialists in the various departments of medicine and surgery. When we read that "no means of investigation which would demonstrate the truth, by any diagnostic device whatever, should be omitted, no instrument of precision should be left unused, no matter how troublesome that use might be to the examiner, no diagnostic device should be passed untried, if by aid of instrument or art *one single fact* could be established with certainty which otherwise was only probable," (*a*), &c., we cannot but wonder who will be competent for these things.

We all recognise the fact that the examination of a candidate for insurance is a problem in diagnosis, and often by no means an easy one, even after many years of experience; it is also a problem in prognosis, a still less easy one, demanding the most careful consideration; it involves also the recognition not only of disease which is, but of disease which is to be in the future, and these forecasts demand the highest knowledge and the highest intellectual faculties. To make such an examination and to solve the problem which may arise must take time, and must weary the patience not only of the examiner, but of the examined; accordingly we cannot but think that an intermediate course is the only one possible, and that special examinations—microscopic, ophthalmoscopic, laryngoscopic, otologic, sphygmographic, hæmatoscopic, endoscopic, bacteriologic, and so on—must be left to the judgment of the individual examiner, who will apply them in case of need. However this may be, I read (*b*) "that the time is coming, nay, the hour is already sounded by the clock, when those men who cannot, from lack of training, or from lack of perception of need, and duty, be brought to use every means and method of diagnosis in making examinations will cease to be medical examiners." Such views as these will not commend themselves, and will not conduce to the increase of insurance, inasmuch as few candidates will be found ready to submit to such an inquisition.

Now, as regards the examination itself, the insurance offices provide forms for the guidance of the medical examiner. We sometimes wish that the form provided might be a blank sheet of paper; the experienced examiner would often give a better report in this way than by answering a long series of questions, many of which have no bearing on the case in hand. We must not, however, forget that there can be no uniformity in the results unless the various examiners have some such form for their guidance, and that the principal function of the examiner is to ascertain the facts and report the same to the medical officer-in-chief at the head office. It is true he is commonly asked to do more than this, as his opinion on the risk is also desired when he is asked to advise the actuary who knows much better; but the summing up of the whole evidence on the case and the adjudication thereon can only be done by the central authority from an examination of the collected reports of the medical examiner, the agents, the reports of confidential friends, and the opinion of the chief medical adviser.

The forms commonly provide that the essential points shall not be overlooked: they are as follows:—

(*a*)—The family history—heredity.

(*b*)—The past medical history of the proposer.

(*c*)—The results of the physical examination at present.

(*d*)—The general appearance of the candidate.

(*e*)—The occupation, habits, residence and general environment.

It is scarcely needful to observe that as a rule an ordinary case presents no difficulty. The first-class life on the one hand, and the manifestly uninsurable on the other hand, are easily determined; but the intermediate cases are those which will tax all the powers of the examiner. Here we have a great variety of problems to solve—those relating to heredity, the effects of previous illnesses, the probability of their recurrence, diminishing or increasing risks as well as present ones, and the exact value of a personal defect with its results in the future. On all those points the examiner has to give information to the actuary, who alone is qualified to determine what is the money equivalent of the defects reported. It is obvious that even with the first-class life no one is spotless; there is always some risk that the possibility of attaining the age of 98—the limit when, according to the British Life Offices, everyone ought to be dead—may be shortened in some unforeseen way. The contract for assurance payable at 98 or at previous death is accepted by the offices on their own conditions.

These conditions are grounded on the duration of life of the normal man, of good parentage, and with a healthy environment. This is the requisite standard, but how few of us attain to it. The risk accepted by the office is a great one, for who can predict the accidents of contagion, who can forecast a fatal attack of pneumonia? Many years ago I was asked to examine a spare man with a family history of phthisis. In spite of my recommendation to accept the risk, it was declined. Fifteen years later the proposal was renewed, the applicant being quite well, and having had no illness during the interval. The risk was then accepted, the first premium paid, death occurred from pneumonia a few months later, and the widow derived much benefit from the two thousand pounds on which one premium only had been paid. It should be generally admitted that every person should be allowed the privilege of insurance unless good cause to the contrary can be shown. The object of the medical examiner is not to endeavour to reject an applicant, but whilst safeguarding the company for which he acts, he should not decline the risk without very good reason, and should not expect that every candidate for insurance should attain the standard of the first-class life both by heredity and environment. The vital stamina may be deficient or the environment adverse, and yet that particular person may attain a good age and prove to be a profitable client. I was once told by a robust-looking gentleman of over 70 years of age that he was the only surviving member of a family of seven, who had died from phthisis, and that he was in early life declined insurance because of his family history.

The most important questions of heredity relate to cancer and tuberculosis. On these two points much information is given in the most recent data of the Scottish Widows' Fund, (*a*) from which the following conclusions seem to be justified:—

1. The registered increase in the number of deaths from cancer is undoubted.

2. After allowing that this increase is not wholly real, but may be accounted for, to some extent, on the assumption that the true nature of obscure cases of malignant disease has been recognised with ever-increasing certainty in recent years, and that as a consequence, the statement of death has been made

(*b*) *Ibid.*

(*a*) "The Causes of Death among the Assured in the Scottish Widows' Fund, 1874-1894," reported by Claud Muirhead, M.D.

with greater precision than had been formerly the case, there remains a large real increase to account for the large and progressive mortality from this disease.

3. The age period at which death from cancer is most frequent is gradually declining according to the Scottish Widows' Fund returns.

4. The average age at death from cancer among our members declined by two years from 1874–80 to 1888–94, as contrasted with a rise in the average age at death from all causes of a little over two years.

5. The office returns mark an *decrease* in deaths from *internal* cancer of 7.70 per cent., and an *increase* in deaths from *external* cancer of 18.89 per cent., of the percentages in the first septennium as contrasted with the third.

Dr. Muirhead further remarks that "during the twenty-one years under observation, cancer as a cause of death among our members aged from 45 to 65 has made rapid and startling progress."

As regards hereditary predisposition to phthisis, it has been sought of late years to deny that such a factor exists at all, and that all cases of phthisis should be attributed to direct infection. From an examination of the data it is stated that "the logical conclusion is that, in the adjudication of a proposal with a family history of phthisis, while we cannot discard from our minds altogether such history as a predisposing cause of the disease, we must attach a much less degree of importance to it than has been the practice in former years," prior to the discovery of tubercle bacillus. Not more than 35 per cent. of the consumptives exhibited any family predisposition to phthisis.

A history of pleurisy, as suggestive of tuberculosis, has recently assumed a grave importance, and the latest dictum is that of Dr. William Osler, (*a*) at Oxford, who states that "during the last twenty-five years the evidence has been accumulating in favour of the tuberculous nature of a large proportion of all cases of simple sero-fibrinous pleurisy. The exact percentage is hard to determine, but, in the absence of pneumonia or sepsis, the very existence of a pleural exudate is in itself sufficient to raise a suspicion of tuberculosis."

Hæmoptysis is a non-infrequent occurrence in those who have no other evidence of lung disease, but it is rightly regarded with much apprehension, and it is usually safe to act upon the assumption that there must be more or less active disease in the lung as its cause. Of course the spitting of blood may not be hæmoptysis of the graver kind, but it is usual to decline any proposer until there has been no return of the hæmorrhage for seven or ten years, after which period, the applicant having reached the age of 35 or 40 and being in good health, he may be accepted as a good life.

Other questions of heredity relate to insanity, diabetes, gout, cardiac conditions, and so on. Of these I remember a notable case of a young lady who after having been a diabetic for some years, was accepted by an insurance examiner as a first-class life: within a very few weeks, she died after a few hours of coma. This lady's father had died of tubercular phthisis after some ten years of diabetes, and a brother has since died from acetonæmic coma as a sequel of diabetes.

Concerning the heart, it is only to be expected that such hereditary maladies as rheumatism and gout should be frequent antecedents of heart disease. It is commonly understood that rheumatic fever in a parent predisposes not only to the same disease in the offspring, but to chronic defects of the heart, even although there may be no history of an attack of acute rheumatism. Hence the insurance offices very rightly attach great importance to the question relating to rheumatic fever.

Diseases of the nervous system must be regarded as likely to be of influence in the offspring. With a family history of well-marked neuroses it would not be safe to accept the risk unless the proposer had reached middle life and had not developed previously any indications of a neurotic tendency. The subject of insanity and epilepsy in relation to life insurance has recently been very exhaustively summarised by Sir W. R. Gowers. (*a*)

As regards the physical examination of the applicant, the most important and obvious questions relate to the height and weight. The men of moderate stature, ranging from 5 ft. 6 in. to 5 ft. 9 in., are considered to be the most capable, with an average weight of 10 st. 4 lb. to 11 st. 10 lb. As regards the practical estimation of these, it is interesting to note that the heels of the boots are considered to approximately counterbalance the weight of the clothing, so that the person may be measured and weighed in the usual garments in which he appears. It is commonly the rule to allow a margin of 15 or 20 per cent. on either side of the normal average as consistent with good health and good constitution, but anything over this margin suggests the perils of obesity, and a marked underweight suggests the possibility of phthisis. Any difficulty arising from over-weight, all other points being good, may be arranged by the recommendation of an endowment policy payable at a certain age, the insurance being then for a short term of fifteen or ten years. This gets rid of the fact that those of over weight tend to die prematurely of apoplexy, heart disease, atheromatous degeneration of the blood vessels, and having poor resisting power, do not throw off the effects of serious ailments as well as those of normal weight.

Dr. Muirhead (*b*) remarks that "light-weights are looked upon as undesirable risks, because, being usually of a nervous constitution, they take affairs of life more seriously than others, and are predisposed to early death from nervous breakdown and tubercular complaints . . ." The investigation of 524 schedules of males who had died of phthisis, when compared with 502 schedules of those who had died of apoplexy, "corroborates the popular opinion that men of light weight exhibit a special proclivity to phthisis, and that over-weight, while not excluding the possibility of the individual falling a victim to lung disease, is much more commonly associated with disease of the nervous system than with phthisis; so that very light weight in a candidate for assurance must always be regarded by the medical examiner as a danger signal, warning him to be more than usually vigilant in his investigation of the condition of the respiratory organs."

The same author also directs attention to the fact that the prevalence of consumption is by no means confined to persons under middle life, inasmuch as phthisis is a potent cause of death amongst the older members. The statistics of the Scottish Widows' Fund directly contradict the popular belief that this disease belongs to the period of youth and young manhood, and is rarely encountered after 45 years of age.

I well remember a case illustrating this point some years ago. The wife died from phthisis at early middle age, one after another of her children followed, then the wife's sister living in the same house, and last of all the father developed an attack of tubercular pleurisy at about the age of 70, from which he died after a comparatively short illness.

It has been remarked (*c*) that "there is more certainty about the result of examination of middle-aged and elderly applicants whose habits are formed, and who have passed through the dangers and risks of early adult life. There are, however, some special difficulties and pitfalls to be avoided in the examination of these lives."

The question is commonly asked whether the apparent age is in agreement with the ages stated. Now this appears to be one of the superfluous questions which might well be deleted from the form. The answers to it must be absolutely unreliable and vitiated by the common experience that some look old whilst young and never look older, some appear to be born looking

---

old, and others grow old but still look young. The question as to resemblance to which parent is another which cannot be of any reliable assistance, and must commonly depend upon the statement of the proposer, unverified by the medical examiner.

The chest measurement is usually asked for, but there must be many fallacious measurements in the case of women applicants encumbered with much clothing and often considerable collections of loose fat. Tables of these measurements (*a*) show that the medium circumference of the chest varies from 33½ inches in a man of 5 feet up to 40½ inches in a man of 6 feet. Approximately the chest measurement should not be less than half the height; that is to say, a man of 5ft. 6 in. should measure not less than 33 inches. "A good chest expansion is a great safeguard against pulmonary tuberculosis, and a range of expansion from forced expiration to forced inspiration of 2 inches at 5 feet height and 3 inches at 6 feet height respectively should be the minimum." Women commonly weigh less than men up to a height of 5 ft. 7 in., but over this they may be more.

The problems associated with the examination of the heart are many and of the greatest importance. On the one hand, there can be no doubt that many applicants are rejected on account of supposed heart disease, and *vice versa* some heart defects may escape observation. Ephemeral murmurs may be mistaken for those of organic disease, and organic murmurs are not always indicative of serious defect. The absence of a bruit is not sufficient evidence that there is no organic defect, and the presence of a bruit does not necessarily render the proposer ineligible. Commonly the mere existence of a cardiac murmur has been considered sufficient to exclude an applicant from insurance, but of late years it has been argued that even well-marked examples of valvular disease may be accepted at an increased premium. The large variety of murmurs of varying intensity and diffusion commonly classed as hæmic would obviously suggest the postponement of the application for three or six months pending the results of treatment. A cardio-respiratory murmur at or outside the apex may be easily mistaken for that of organic disease, and has frequently been the reason for rejection of a candidate. Neither of these murmurs should be a sufficient reason for a definite refusal of the proposal. But on the other hand, if there exists a definite systolic murmur at the apex believed to be of organic origin, and even if there should be no other evidence of heart defect or of weakness of circulation, the uncertainty of prognosis in such cases must render the applicant ineligible for insurance. It must be impossible for the medical examiner to advise the office to accept the risk when a sudden heart failure is at any time a by no means remote possibility. The presence of a murmur of mitral or aortic stenosis or one of aortic regurgitation will be still more emphatic in causing rejection. In spite of the fact that cases of aortic regurgitation and of mitral regurgitation with good compensation have been known to continue for very many years, and the patients sometimes survive to a good old age, yet the uncertainty of such conditions, and the facility with which failure of the compensatory conditions may arise must give no hesitation in absolutely declining to entertain an acceptance of such risks. A diagnosis of hypertrophy, indicated by a supposed displacement of the apex beat, has often given rise to a difficulty. Here there are many fallacies due to obliquity of ribs and other causes which may lead the examiner into error. There are many conditions where, in the absence of a murmur, the position of the apex beat, its character, and that of the sounds, the rhythm and regularity or otherwise of the heart-beat, may be such that the integrity of the heart muscle may be gravely questioned; in all such a rejection of the proposal is inevitable. The cases in which fatty heart may be suspected give much ground for question, for if all cases are rejected in which the impulse is feeble and irregular, it will lead to the loss to the company of many good lives.

Of the pulse-rate there can be no rigid limit. Nervousness is not confined to women, and a quick pulse is often the result of many trivial and temporary causes. Cases of persistent tachycardia or bradycardia should lead to enquiry as regards the possibility of brain lesions, of arterio-sclerosis, fatty heart, Graves' disease, or excess of alcohol and smoke.

In connection with diseases of the arteries and aneurism it is well to remember that arterial murmurs of an ephemeral character may be due to the pressure of unusually well-developed muscles. It was once my duty to report on an eminent cricketer who had been declined insurance in consequence of a murmur below the clavicle, which was no doubt due to this cause. There was no other defect, and the risk was duly accepted.

The state of the genito-urinary organs presents many questions. Syphilis and gonorrhœa appear to be remarkably rare in applicants for insurance, and hence the need for critical clinical observation on the part of the observer, and especially as to the veracity of the applicant. Of course, no case can ever be accepted so long as sugar or albumen is found in the urine, but a temporary glycosuria or a temporary albuminuria would not permanently exclude the candidate from insurance. A passing glycosuria in middle life is quite as common as what is called cyclic albuminuria in the youth, and although it cannot be discreet to accept the risk in the presence of either, the disability may be only temporary and need postponement of the proposal for three or six months.

The general appearance of the proposer presents many points for observation; anæmia, or cyanosis, injected capillaries of the cheek, œdema of eyelids, an icteric tint, or contracted pupils, the condition of the tongue, throat, gums and teeth, the proportion of muscle to fat, and the patient's bearing under examination, as unusual reticence and sometimes a craving for morbid accuracy may give information of an important character. All these points should be passed in mental review and noted when needful.

The older forms commonly make an inquiry as to the temperament of the proposer. Now the modern medical man is not educated in the classical temperaments, and has little regard for them. If he attempts an answer to the question he does so in a casual kind of way, deeming it of no importance. Dr. Stillman (*a*) has the audacity to devise a new series of temperaments of his own. He cuts down the classical four—lymphatic, sanguine, bilious and nervous—to three, and those he designates on an anatomical basis—motive, vital and mental. He remarks that "when either of the temperaments exists in excess, the result is necessarily a departure from symmetry and harmony both of mind and body, the one always affecting the character and action of the other. Perfection of constitution consists in a proper balance of temperaments, and whatever tends to destroy this balance should be avoided." We are told that in this country diverse nationality and parentage render it more and more difficult to find typical specimens of the normal temperaments, and that the same individual at different ages may be classified under different headings. According to age, the child approximates the sanguine or vital temperament; the mature adult the bilious; while advancing age produces a tendency either to excess of the nervous or phlegmatic elements. We think that the whole question of temperaments, and the supposed liability to particular forms of disease associated therewith is so beset with fallacies that they are of little use in estimating the probable duration of life or liability to disease.

The words diathesis and cachexia are also of little use from the insurance standpoint. Few cases with such chronic ill-health as would justify the appellation "cachectic" are likely to apply for insurance, and these would be at once recognised as ineligible. As regards the strumous, gouty and rheumatic diatheses,

(*a*) Stillman, "Life Assurance Examiner," 1888.

there will be information derived from the family history.

The information as regards the vital statistics of the family is at all times a little difficult to obtain; the want of knowledge and the fallacies of memory greatly test the patience and the tact of the examiner. It is not surprising that people know so little of the causes of death of their grandparents, whom often they have never seen and of whom they have rarely heard; beyond the father and mother the information can only be approximate, but it becomes of importance when either parent has died in early life. It is also not to be wondered at that many applicants know very little of the cause of death of elder brothers and sisters whom they may have never seen, and of whose diseases they can personally know nothing. Any person of intelligence should be able to state the cause of death of brothers and sisters who have been known to them, but it is not surprising that the non-medical mind should often fail in giving anything like an accurate statement of events which may have occurred many years previously. The examiner has to be cautious in the acceptance of these statements, and especially when there is method in the want of knowledge and apparent want of memory, which may be more feigned than real.

We often hear of insurance without medical examination, and of the alleged uselessness of medical selection. No doubt there are many fallacies into which the most careful examiner may fall, and the most honest judgment may be neutralised by the unavoidable accidents and uncertainties of life, but it has been shown by the statistics of the Scottish Widows' Fund(*a*) that an enormous disproportion is observed between the rates of mortality from consumption of those insured and those recorded by the Registrar-General. The deaths from consumption at all ages amongst the selected lives were 81.15 per 10,000, as compared with 178.29 during the ten years 1881-90, as given by the Registrar-General. This disproportion is clearly due to the medical examination which each candidate has to undergo before being admitted to the benefits of insurance. It is also scarcely necessary to remark that the mere presence of a medical examination prevents the application of the large body of persons who are known to have organic and other defects which would render their acceptance improbable. No one likes to be rejected, and few will make any overtures if they have any suspicion that they may not be acceptable.

Much disputation has existed from time to time as regards the fee which the offices should pay for the medical service rendered. It has always appeared to me that there can be no rational excuse for the practice of cutting down the fee to one-half because the amount to be insured is small. The examination is the same whatever the amount of the insurance may be. No honest medical examiner can proportion his examination to the size of the fee or to the sum insured. This will always take a considerable time and require the same careful consideration, and it is not necessary that the medical examiner should know whether the proposal is for one hundred or ten thousand pounds. So also as there is no reason for cutting down the fee for the smaller sums, neither is there any for doubling it in the case of the larger amount. It is true the responsibility appears to be greater; but this should have no influence in the examination, which is presumed to be in all cases complete, thorough and honest.

CASE OF CEREBRAL ABSCESS FOLLOWING ACUTE MASTOIDITIS.

PEYTON T. B. BEALE, F.R.C.S.(*b*)

THE patient, a man æt. 22, was admitted to the Great Northern Central Hospital, at 11 p.m., on October 20th, 1906.

He complained of pain in the left ear, slight headache, vomiting after food, and at times rigors. There was a small amount of pus in the left external auditory meatus, and a very slight amount of pain on firm pressure over the mastoid antrum, but no redness or œdema in this region. There was no bulging or drooping of the auricle. On the pus being cleared from the meatus, numerous granulations were seen in the floor. The membrana tympani was slightly congested and perforated at the lower and back part, from which pus exuded. There was very slight tenderness on pressure over the left jugular vein. There was no sign of intracranial mischief. The pupils were equal, and reacted normally, and there was no squint. The knee jerks were normal and equal; the plantar reflex was flexor. No paralysis of muscle anywhere. The temperature was 102, pulse 104 respiration 24. The other organs were all healthy; urine normal. The history of the case was as follows:—

A month previous to admission patient had a painless discharge from the left ear which lasted five days and passed off. The discharge began again six days before admission, and at first was painless, but after the first day pain began and became very severe. Three days previous to admission pain in the ear became very severe, patient had a rigor, and the temperature rose to 103 degrees, and he began to vomit his food. From this time until date of admission the temperature kept up, rigors recurring at intervals and vomiting continued. Previous illnesses, none.

Mr. Beale was at once called to the case, and on his suggestion the antrum was opened in the usual way by Mr. Clark, senior house surgeon. The bone here was hard and like ivory, and the antrum lay deep, but when opened creamy pus came out with considerable force. The outer wall of the cavity was completely removed by mallet and chisel, and the middle ear washed out but not opened. The cavity was packed with gauze, and the wound partly stitched up.

Next morning (October 21st) the temperature was normal, and the patient felt better than he had done for days. The plug was removed, and the cavity washed out with lysoform (1 in 20), the lotion passing through the middle ear and out through the external auditory meatus. In the evening he had two slight rigors, and the temperature rose to 103.6 degrees. Slight weakness of muscles of left side of face was noticed.

As the temperature kept up, the patient was again anæsthetised, and Mr. Beale exposed the lateral sinus, but found it healthy, so the cavity was plugged, and the wound closed again. In the night patient had two rigors, but next morning (October 22nd), the temperature was normal, and the patient felt very well.

After this there were no more rigors, the weakness of the left side of the face disappeared, the discharge from the wound became less, and the patient was able to walk about the ward.

On the morning of November 4th patient had a right-sided convulsion. The twitching began in the right hand and arm, and spread to the right side of the face and the right leg, but did not spread to the left side. He did not lose consciousness, and there was no squint or aphasia. The convulsion lasted about two minutes, and afterwards there was paresis of the affected muscles, which slowly passed off. The temperature remained normal and the patient took his food well, did not complain of headache, and there was no vomiting.

The patient remained perfectly well until next afternoon (November 5th), when he had a second epileptiform attack, much less severe than the last, and beginning in the right hand in the same way. After this there was complete right hemiplegia. The ocular muscles were unaffected, but the orbicularis palpebrarum was paralysed. Sensation on the right side was perfectly normal. There was no aphasia or hemianopia. The right knee jerk was increased, and the plantar reflex was extensor. There was slight ankle clonus present. The pupils were equal, medium, and reacted normally. There were no retinal changes present. The patient's mental condition was perfectly clear. The temperature remained normal, and the pulse varied between 90 and 100 per minute. A

(*a*) *Op. cit.*, p. 39.

(*b*) For the notes of this case we are indebted to Mr. Clark, Senior House Surgeon.

diagnosis of cerebral abscess in the middle of the left Rolandic area was made.

On November 6th the patient was trephined by Mr. Beale. A horseshoe-shaped incision was made, and the scalp turned down from the parietal eminence on the left side. The pericranium being turned back, a piece of skull was removed by a crown trephine over the middle of the fissure of Rolando. The dura mater when exposed looked healthy, did not bulge, and the normal pulsation was visible. A small incision was made in the dura and the brain explored in every direction with a small grooved director, but no pus found. Then an exploring syringe was used in the same way, and some of the ventricular fluid drawn off which was perfectly clear. The dura mater was separated from the skull down to the base, but no pus was found anywhere. The scalp was sutured in position, a small gauze drain being left leading down to trephine hole. The patient suffered a good deal from shock after the operation.

After this the temperature rose steadily to 101.4, and the patient vomited several times. The pulse was never under 80 per minute. He developed aphasia and gradually became more and more drowsy, though never unconscious. The right knee jerk was lost, and the plantar reflex remained extensor. There were no more convulsions.

On November 9th patient was again trephined by Mr. Beale about 1½ inches below and behind the previous opening, over the posterior end of the fissure of Sylvius. The brain was explored here in the same way as before, but nothing found. On pressure being made over the scalp in the region of the former opening some suspicious-looking fluid was found to exude from the edge of the scalp flap, so the trephine hole was again exposed. A bead of pus was found exuding from the centre of the opening, and when a sinus forceps was introduced, about half an ounce of thin greenish yellow, foul-smelling pus escaped. The abscess lay at least ½ inch below the cortex in the middle of the Rolandic area, as previously diagnosed. The cavity was found to have a fairly definite wall and was syringed out, a rubber drainage tube being left in. The scalp was now sutured in position, a hole being cut in the flap to admit the drainage tube. The patient stood the operation very well.

Next morning the temperature was normal, and the patient began to take notice of things, though he was unable to speak. There was still complete right hemiplegia.

November 13th.—The temperature keeps normal. No change in the paralysis. Patient is perfectly intelligent, and can now say "Yes." There is still a large quantity of pus draining from abscess cavity.

November 20th.—Patient now talks fairly well, but slowly, and at times seems at a loss for words. Right side of face still weak, but power returning rapidly. Arm and leg still paralysed. General health excellent.

November 25th.—There is now slight movement of thigh muscles, and the arm seems less limp than before. Right side of face recovered. There is still a fair-sized cavity in the brain, but less pus being discharged. The drainage tube is still in. The mastoid antrum is now practically healed up.

November 30th.—Patient now talks as well as ever. He is able to move the thigh muscles, but not the leg or foot. The arm is still paralysed, but the muscles react to mechanical stimulation. There is now only a small gauze drain leading into the almost closed abscess cavity. The ear is practically cleared up.

The general condition of the patient is now very good, and except for paralysis he is perfectly well.

REMARKS BY MR. BEALE.

Mr. Beale said that the case was an unusual one, because the cerebral abscess could not be said to be directly in continuity with the suppurative process in the middle ear or in the antrum.

At the second operation, when he investigated the lateral sinus, he also made certain that there was no pus near it, or in connection with the brain close to the temporal bone, and the progress of the case during the next 12 or 13 days fully bore this out, for the patient appeared to be getting on perfectly well.

At the first trephining on November 6th Mr. Beale found no abscess. At that time he believed his exploring instruments had passed close to an abscess, but had not perforated its somewhat tough and thick wall. Therefore he employed a needle, but still was unable to get any pus. His opinion now was that the pus was very much deeper than he at first believed, and this opinion was quite justified by the large extent of the paralysis which was present, indicating the presence of damage not in the cortex, but deeper, where the motor fibres were packed closely together. Moreover, the cortex of the Rolandic area appeared quite normal, and not as it ought to have appeared had there been a large abscess within an inch of it.

As regards prognosis, everything now seemed favourable to complete recovery.

NOTE ON ADENOIDS AND NASAL OBSTRUCTION.

By WILLIAM LLOYD, F.R.C.S., L.R.C.P.E.,
Surgeon-in-Charge of the Nose, Ear, and Throat Department, Kensington General Hospital; Aural and Laryngeal Surgeon, St. Pancras and Northern Dispensary, &c.

It is a matter of clinical experience, both to myself and all other throat and nose specialists, that numbers of patients who have been operated on for adenoids return to us after a short time with their symptoms unrelieved.

The explanation of this disappointing fact is that two or more causes of nasal obstruction co-exist, and the mere removal of adenoids improves for a time, then the trouble of general obstruction asserts itself again, and the whole symptoms of adenoids are reproduced.

Causes of Nasal Obstruction.

In considering the causation of nasal obstruction, one is helped by remembering that the nose is bounded by bony and cartilaginous walls, covered with mucous membrane, rich in glands; also that the antrum and other accessory cavities communicate with the nasal cavities, and malignant growths from these sinuses readily find their way into and block up the nose. For practical purposes the following classification is simple, and includes most of the conditions which cause nasal obstruction.

I.—*Conditions originating in the mucous membrane and its glands or in the periosteum.*

Adenoids.
Hypertrophic rhinitis.
Mucous polypi.
Vascular growths and papillomata.
Gummata.
Carcinoma and sarcoma.

II.—*Conditions of the Bones or Cartilages.*

Displacements or the angular projections of fractures of the septum nasi.
Congenital deformity of the septum.
Exotosis or ecchondrosis.

III.—*Other Conditions.*

Congenital smallness of nasal cavities.
Congenital abnormalities.
Hæmatoma.
Abscess.
Foreign bodies and rhinoliths.
Cicatricial contraction of nares.
Synechial.
Enlarged Eustachian cartilages and pterygoid plates.
Meningocele.

It is the aim and object of the present paper to deal with—

(i.) Adenoids.
(ii.) Those cases which have the look and symptoms of adenoids without any being present.

Omitting the effect on the general health and development of the child, the symptoms of adenoids can be conveninetly put under three headings :—

Nasal, Aural, and Pharyngeal.

The symptoms due to adenoids are not dependent merely on the size of the swelling any more than all the symptoms of enlarged tonsils are the result of its overgrowth. Patients are frequently seen with very large tonsils with next to no symptoms, or there may be only small tonsils, which are constantly becoming inflamed.

The same is true of adenoid growth. It may attain a very considerable size, and apparently cause little trouble. Whether it will give rise to trouble depends on the extent to which it is associated with nasal catarrh, and this catarrh causes a chronic hypertrophy of the inferior turbinates. The nasal cavities may be partly blocked by the mere size of the large pad of adenoid tissue, but more frequently as a result of the spreading of the catarrh, which is liable to exacerbations, and the children are described as always catching colds; therefore it is the hypertrophic rhinitis more than the mere lumps of adenoids which give rise to the characteristic nasal obstruction, and when the mouth-breathing has persisted for a long time definite changes are brought about in the face, chest, etc. The facies is so peculiar and distinctive that the condition may be evident at a glance.

2. *Congenital Narrowness of Nasal Passages.*

Hundreds of children are brought or sent to every out-patient department with symptoms exactly simulating adenoids. All the signs are present which make up the complete picture of an adenoid case.

On examination, the nose is small and narrow, and frequently the inferior turbinate body appears jammed in between the septum and outer wall. The naso-pharynx is free of adenoids, but the space is narrow and pinched, barely admitting the tip of your finger; the soft palate and pharynx nearly touch. These cases are as common as cases of real adenoids, and it is impossible to doubt that a large number are subjected to the operation for adenoids who do not require it. What should be done to these cases? The majority should be left alone, as there is nothing more than inconvenience and occasional discomfort. At puberty the nasal cavities, in common with other passages, commonly enlarge. If the obstruction is so bad as to interfere with the general health or causing deafness, then a part of the turbinate must be removed with a spokeshave or cutting forceps.

Conclusions.

With the above formidable list of cases of nasal obstruction, which often co-exist, one can readily understand the causes of failure in the hands of operating practitioners who are not conversant with the technique of anterior and posterior rhinoscopy, whereby any other pathological condition complicating post-nasal growths might be recognised and dealt with if the operation is to be successful.

No surgeon would operate on the abdomen for intestinal obstruction without knowing all its causes and the various methods of dealing with them, yet the same surgeon will operate on nasal obstruction not knowing how to examine the nasal cavities, and takes it for granted it must be adenoids.

I have met with patients who have been subjected to two and three operations for the removal of adenoids with no benefit, the reason being, as I have pointed out, other causes being associated and overlooked depending upon imperfect examination.

All this meddling tends to discredit nasal surgery.

THE OUT-PATIENTS' ROOM.

ROYAL FREE HOSPITAL.

Charcot's Joint.

By Joseph Cunning, B.S., F.R.C.S.

Among the out-patients was a man æt. 52, who complained of pain and swelling in his right knee; this had lasted on and off for nine years. There was no history of injury, and the symptoms were stated to have begun gradually. On examination the right leg was seen to be markedly deflected outwards; in fact, there was one-sided knock-knee. This, the man said, had slowly developed during the last nine years. There was a swelling occupying the upper part of the synovial pouch of the knee-joint, and obliterating the grooves on either side of the patella. The sign of fluctuation proved this to be fluid; during examination tenderness was elicited. Proceeding further, it was found that there was great overgrowth of the tuberosities of the tibia, laterally and posteriorly, and that the synovial membrane was studded with tough villous processes.

The movements of flexion and extension of the joint were unimpaired, but were accompanied by grating, which was not only palpable, but audible. Abnormal lateral mobility was also present.

Mr. Cunning pointed out that this case was either one of osteo-arthritis or Charcot's disease, two diseases which belonged to the same type, in which the changes in the joint structures were similar, but these were carried to a further degree in the case of Charcot's disease. He thought that the slow onset of the malady, and the amount of pain from which this patient had suffered rather suggested he was the subject of osteo-arthritis, but on the other hand, the exaggerated changes in the shape of the limb, the amount of wearing away of the external condyle, and the overgrowth in the head of the tibia, all pointed to Charcot's disease.

The patient was further examined,and found to have an Argyll-Robertson pupil; there was also absence of knee-jerks. With reference to the former, Mr. Cunning pointed out that the best way to examine for absence of the light reflex was to cover one eye, and at the same time watch the other. If a light reflex is present the observed pupil dilates when the other eye is covered, contracts when it is uncovered. He considered that this method averts a fallacy which may creep in when other methods are used: if both eyes are covered, and then uncovered, contraction due to accommodation may occur, and deceive the examiner, for the patient involuntarily accommodates to the surgeon's face or the light he may be holding.

The conclusion arrived at was that this was clearly a case of Charcot's disease.

Mr. Cunning was asked what was the ultimate fate of these joints, and said that the fluid in them subsided from time to time, and if an apparatus were worn which prevented abnormal mobility, a fairly useful joint resulted, though the patients were liable to exacerbations in the way of swelling.

Then very marked changes occurred in some of them in the formation of bony plates in the synovial membrane, so that the joint became more or less ankylosed by a sort of protective armour.

Mr. Cunning also pointed out that a Charcot's joint may be the very first sign discovered in a case of locomotor ataxia, preceding the lightning pains, absence of knee-jerks and Argyll-Robertson pupil.

OPERATING THEATRES.

ST. THOMAS'S HOSPITAL.

Injury to Skull, Trephining, Œdema of the Brain.—Mr. Edred Corner said the case he was going to operate on was that of a boy who with several others was standing under a tree throwing stones at birds, when a stone thrown by another boy came down and hit him on the head. He had sustained a compound fracture of the vault of his skull over his left parietal region. A week had now passed since the accident, during which the scalp wound had suppurated, and the boy had become drowsier and more unconscious. He had had little or no fever, and the pulse was not rapid—84. The question of diagnosis lay between an extradural or cerebellar abscess and meningitis. The history and the onset, the absence of fever and the quickening of the pulse seemed to indicate the abscess. The absence of localising symptoms indicated the meningitis. It was obvious that if left alone the boy would die, so that it had been decided to trephine over the wound in the skull, because if an abscess was found and opened the boy might live. Whilst the scalp was being shaved and cleansed, Mr. Corner pointed out that practically no anæsthetic was required. The wound in the skull was more or less punctured, and a probe was easily passed right through. Cerebro-spinal fluid escaped at first through it, but soon none came away, probably because the swelling of the subjacent brain had blocked the aperture. To expose the field of operation a flap of the scalp was turned down with its base directed towards the ear. This flap was made large to give full exposure. The knife cut down to bone at once, so that the flap was reflected before any vessels were secured. The hole in the skull was seen to be irregularly punctured. The pericranium was reflected after being incised in a cruciform manner. An inch trephine was used to take away the bone in a disc, the centre of which was the wound in the skull. Now that the disc was removed, it could be seen that there was no extradural abscess, and that the dura mater had been perforated by the falling stone. The dura mater was next incised crucially and the brain bulged. The bulging part presented a curious appearance. It was very pale, œdematous, and marbled by blue veins. There was no fluid or pus worthy of note within the cavity of the dura mater. There was a small ragged tear on the surface of the brain where it had been wounded by the stone. The brain was explored with trocar and cannula. A cerebral abscess of traumatic origin, was, he said, always formed just under the seat of injury, so that the trocar was plunged straight into the brain. Unfortunately for the boy there was no result. Further explorations failed to find any abscess. And there was nothing left but to suture the flap of scalp in its place. In pointing out the reason of the failure and why the boy must die, Mr. Corner said—Firstly, the alternative and provisional diagnosis of extradural or cerebral abscess was wrong. Secondly, the alternative diagnosis of meningitis, in the ordinarily accepted sense of the word was also wrong. Thirdly, there was found. what he did not expect, a wound of the brain, accompanied by a pale and œdematous, rather than an inflamed, brain. This condition was one which many do not believe in, and to which has been given the name of "spreading œdema." It was doubtless of a septic or infective origin in this case, though not necessarily so in others. At its commencement, it was probably inflammatory. But, as was seen, the brain was pale and œdematous, not red and hyperæmic, as ordinary inflamed tissues. Probably the "spreading œdema" in the brain represents what would be a cellulitis in other tissues. This cannot be treated in the brain, and the boy must die.

Apollinaris Water.—We are asked to announce that the Grand Prix has been awarded to Apollinaris Water at the Exposition Coloniale, Marseille.

TRANSACTIONS OF SOCIETIES.

ROYAL ACADEMY OF MEDICINE IN IRELAND.

Section of Obstetrics.

President—R. D. Purefoy, M.D., F.R.C.S.I.
Sectional Secretary—H. Jellett, M.D., F.R.C.P.I.

Meeting held Friday, December 14th, 1906.

Dr. R. D. Purefoy, President of the Section, in the chair.

NEW FORM OF PESSARY FOR USE IN UTERINE PROLAPSE.

Dr. **Seymour Stritch** said he had been obliged to devise a pessary which would support the uterus, in a patient æt. 80, without pressing on an ulcerated cervix. He accordingly had a pessary made in the form of a ring, supported by a vaginal stem, from the vulvar end of which tapes are attached, for fixation, to a waistband. The ring (made by Down Bros.) can be hinged against its stem to facilitate its insertion, and when in position can be locked at the required angle to the stem. The uterus hangs within the ring free of pressure irritation.

Dr. **Hastings Tweedy** said they should be grateful for any device which would ameliorate the suffering in prolapse of the uterus in the aged when operation was impossible. He thought the pessary should get a fair trial.

Sir W. **Smyly** agreed with Dr. Tweedy. In two very important points—the joint and the waist attachments—Dr. Stritch's pessary was a distinct improvement on former ones.

Dr. **Alfred Smith** expressed his intention of trying the pessary in his own practice.

The **Chairman** also commended the pessary.

UTERUS WITH CANCER OF CERVIX AND FUNDUS.

Dr. **Henry Jellett** showed a uterus with cancer of both cervix and fundus. He said that he showed the specimens rather from their pathological interest than as an operation specimen. One of the indications in the past for supra-vaginal amputation of the cervix was said to be cancer of the cervix, and he thought this specimen showed the untenable nature of such a position. The specimen was also a rare one, and Cullen in his work on cancer of the cervix only recorded half a dozen cases. Cases of cancer occurring at both the fundus and the cervix might be divided into two classes:—First, those in which the two cancers were independent of one another. Such cases were difficult to allocate with certainty, since, unless the two cancers were of a different nature, it was difficult to say that they did arise independently of one another. The mere fact of a cervical and fundal cancer co-existing without macroscopic connection did not afford evidence that the two were dissociated. The second class of case was that before them, in which it was possible to trace definite connection. In the present case, of a patient about fifty-four years of age, he had operated for cervical cancer, and had no reason to suspect fundal cancer. The first thing he saw on opening the abdomen was a slight adhesion of the intestines to the fundus. The operation was a fairly radical one, and he regretted to say the patient was unable to stand it, and died from the shock fourteen hours after. The operation had to be very extensive, on account of the necessity of taking away almost the entire upper third of the vagina. In the specimen before the meeting a fine line of connection could be seen between the two growths, and this presumably followed the lymphatics traversing the muscular wall from one growth to the other.

Dr. **Alfred Smith** said the case reminded him of a recent article on how cancer spread. Cases had been found in which the cancer extended not only through the lymphatics but also by the tiny branching tendrils that seemed to grow out from the primary cancer.

Dr. **Hastings Tweedy** thought it was a great triumph that so much of the vagina had been removed without rupture.

Sir W. **Smyly** said he had seen the operation performed. It was a very radical one, and it was a great pity the patient had not the strength to stand it.

The **Chairman** said the case reminded him of one of his own in which the uterus contained two varieties of cancer, one in the cervix and one deep in the tissue of the fundus, no microscopic or macroscopic connection being between them. The disease in both localities was not very far advanced, and the patient made a good recovery.

Dr. **Jellett**, in reply, said the operation was performed by Werder's method, as described in Cullen's "Cancer of the Uterus." In spite of the fact that it had been abandoned by its originator, it was an excellent operation for the removal of extensive vaginal infiltration. In the case before them the rectum was free, but the bladder was commencing to be involved, and there was considerable difficulty in separating the vaginal wall from the bladder.

OVARIAN CYST.

Sir W. **Smyly** presented a specimen of ovarian cyst. He said the case showed all the characteristics of an ovarian tumour, except that he could not isolate the uterus from the tumour. The uterus moved with the tumour, and, though he thought it was ovarian in origin, he could not make a positive diagnosis. When he opened the abdomen he saw what appeared to be an ordinary ovarian cyst. He incised it, and let out a quantity of pseudo-mucinous fluid. When he had dealt thus with half a dozen cysts, he enlarged the incision, and found the uterus spread out over the front of the tumour, and the round ligament running over the top of it. The pelvic cavity was almost entirely de-peritonealised. When he had almost completely shelled out the tumour he found it impossible to separate it from the uterus, and, even as it was shown, it was impossible to see any line of separation between the tumour and the uterus, so that one would be almost inclined to think—were it not for the characteristics it presented—that it was fibro-cystic tumour.

On the motion of Dr. **Alfred Smith**, seconded by Dr. **Hastings Tweedy**, the specimen was referred to the Reference Committee for a special report.

VESICAL CALCULUS WITH NUCLEUS OF PEDICLE SILK.

Dr. **Alfred Smith** said that about three months after the removal of a large ovarian cyst the patient began to suffer increasing pain during micturition, and her medical adviser was satisfied that she had stone in the bladder. Eventually she came to him. She was so tender that he could not palpate her without an anæsthetic, but when the anæsthetic was administered he found the bladder filled with stone. Having smashed the stone and washed out the fragments he drew out, by the urethra, with the guidance of the finger and forceps, the ligature shown. The natural explanation of how the ligature got into the bladder would be that there was some inflammatory disturbance around the pedicle, but if such were present it would suppose some evidence of pain, but the only pain complained of was that already mentioned.

The **Chairman** recalled a parallel case.

Dr. **Neil** instanced a case in which the patient passed a quantity of pus in the urine some time after the removal of a large myoma, but none of the ligatures came away.

A CASE OF LABOUR OBSTRUCTED BY FIBROID TUMOUR: RED DEGENERATION OF THE TUMOUR.

Dr. **Roulette** read, for Dr. Kinkead and himself, a paper on "A Case of Labour Obstructed by Fibroid Tumour: Red Degeneration of the Tumour." The patient, a multipara, was admitted to the County Galway Hospital, having been thirty hours in labour; a globular tumour, four inches in diameter, was presenting at the vulva, apparently springing from the anterior lip of the os. As the tumour was very vascular, Dr. Kinkead decided to deliver the patient before removing the tumour. Drawing the latter down and forward, he applied forceps and extracted a living child. When the placenta came away he cut the pedicle of the tumour with an écrasure. The patient left hospital quite well on the thirteenth day. The tumour was a typical example of "red degeneration," showing necrosis and congestion. The condition was probably comparatively rare, and was in most cases associated with pregnancy. It usually gave rise to marked constitutional symptoms—pain, weakness, wasting, gastric disturbances. Dr Rowlette believed that the staining was due to a diffusion of the blood pigment consequent on a sudden necrosis of a congested tumour.

Dr. **Henry Jellett** said the Section was indebted to Professor Kinkead not only for his paper, but because he had given Dr. Rowlette, incidentally, an opportunity of making a very important contribution to the pathology of an obscure condition. If the staining in the case was incidental with the staining that would be brought about by the breaking down of the red corpuscles in the blood, by finding a cause for such a breaking down some explanation would be found for the condition. On a former occasion he had suggested that there was possibly some curious bacterial action which brought about the change, but, with or without a previous bacterial invasion of the tumour, some ferment might be found in the tumour that would lead to breaking down of the corpuscles.

Dr. **Hastings Tweedy** congratulated Professor Kinkead on the brilliant way in which he had dealt with the case, and brought it to a successful delivery, notwithstanding the immense difficulties in his way.

Dr. Ashe, Dr. FitzGibbon and the Chairman also spoke.

Dr. **Rowlette**, in reply, said the term "degeneration" as applied to the condition was a bad one; it was not a degeneration, but a necrosis. In none of Fairbairn's cases was any bacterial infection found. If bacteria gained access to the degenerated fibroid it was likely to be quite different from the simple necrosis in the case before them.

The following card specimens were shown:—

Dr. **Spencer Sheill**—Tuberous Sub-chorial Hæmatomata of the Decidua in an early Abortion.

Dr. **Hastings Tweedy**—(*a*) Ovarian Cysts, 2; (*b*) Myoma of Uterus, 5; (*c*) Salpingitis; (*d*) Epithelioma of Vulva.

THE LIVERPOOL MEDICAL INSTITUTION.

Meeting held Thursday, December 20th, 1906.

The President, Mr. **Frank T. Paul**, F.R.C.S., in the Chair.

Mr. G. P. **Newbolt** read notes of a case of PERFORATING DUODENAL ULCER, complicated by abscess of the lung, in a male patient, aged 30 years, who had previously been in robust health. The treatment was by injections of polyvalent serum. Frequent attempts were made to localise the abscess with exploring needles; the abscess eventually emptied itself—on some days, a pint to a pint and a-half of pus being expectorated. Finally the patient made a good recovery. The organism isolated conformed to the type of streptococcus termed S. Salivarius by Andrewes and Horder.

OPERATIONS DURING TYPHOID FEVER.

Mr. W. **Thelwall Thomas** read notes of two cases of surgical operations during the course of typhoid fever—one for perforation and one for appendicitis—both of which had recovered. He drew attention to the fatal character of perforation unless surgically treated, when the recovery rate was 30 per cent. or more. Although in many cases the diagnosis was uncertain—stress would be laid on pain, rigidity, and increased pulse rate; even when in doubt it would be wiser to explore (under local anæsthesia) than to wait until general septic peritonitis had set in. The treatment of the perforation by quick suture or the formation of a fæcal fistula appeared to be the two alternatives; fancy work, such as enterectomy with end to end anastomosis, was not to be recommended; enterostomy had the further advantage of draining and keeping the typhoid intestine at rest. The first patient was a man who had been walking about until a few days before symptoms of perforation occurred; the case was diagnosed as perforative appendicitis and immediately operated upon, with the result that a typhoid perforation was found. The second was a young lady in the third week of typhoid: though a provisional diagnosis of perforation was made, at the operation acute appendicitis was found. Mr. Thomas briefly described two other previous cases in which he had operated for typhoid perforation without being able to save the patients' lives.

The **President** referred to two cases—one illustrating the difficulty of making a certain diagnosis in typhoid perforation; the other, a perforation 12in. from the cæcum three months after the onset of typhoid fever. In the latter case the ulceration was so extensive that the perforation could only be closed by excising it, and the patient died nine days after the operation.

Mr. T. C. **Littler Jones** mentioned a case he had operated upon successfully last July. A Lascar boy was brought to the infirmary at the end of the second day after perforation of a typhoid ulcer. Simple suture of the ulcer was performed and the abdomen cleaned of intestinal contents. The boy was transferred to his ship three weeks afterwards. Perforation was rare in Hindus, and the infection comparatively slight.

The difficulty of diagnosis was illustrated by a case he had seen at Pretoria in a soldier suffering from typhoid and scurvy. The man had taken several strong doses of lime-juice at once, and the consequent colic, rigidity of the abdomen, pain and collapse closely simulated perforation of the intestine. Fortunately the cause was discovered in time.

Mr. Littler Jones agreed with Mr. Thomas that the chances of success depended upon the time that had elapsed since the perforation, and on the speed with which the operation was performed.

Mr. R. W. **Murray** said that better results from operative interference would probably be obtained if as a general rule the bowel at the point of perforation was brought to the surface and a fæcal fistula temporarily established. Such an operation could be quickly performed, and would have the great advantage of allowing the inflamed bowel rest, and affording the ulcerated surface every opportunity of healing.

Drs. W. Carter, T. R. Glynn, R. J. M. Buchanan, T. R. Bradshaw, E. E. Glynn, and J. Hill Abram also spoke.

Dr. R. J. M. **Buchanan** read a paper on

ACUTE LYMPHATIC LEUKÆMIA.

in which he drew attention to the rarity of the disease, and said that in its symptom complex it resembled in many ways an acute specific fever. The blood picture was one quite different from that seen in myeloid leukæmia, and was due to a hyperplasia of definite cell elements. The clinical picture was described and illustrated by an acute case of nine days' duration, in which the symptoms pointed, in the later stages, on the one hand to a morbid blood state, and on the other to an acute abdominal lesion, most probably hæmorrhage into the pancreas. A blood count revealed a lymphocytosis of 528,000 per cubic metre.

The case was under the care of Dr. Schofield, of Southport, to whom Dr. Buchanan expressed his thanks for the notes of the early condition.

The paper was discussed by Drs. E. E. Glynn, W. Carter, and Horter.

Dr. A. **Cassels Brown** read a paper, entitled "Two Forgotten Medical Worthies." The subjects of the paper were Dr. Gabriel Broughton and Dr. William Hamilton, both of whom played somewhat important parts in the early struggles of the "Company" in India.

A most cordial vote of thanks was accorded to Dr. Cassels Brown for his most interesting paper.

BRITISH BALNEOLOGICAL AND CLIMATOLOGICAL SOCIETY.

Meeting Held Thursday, December 13th, 1906.

The President, Mr. H. Shirley-Jones, M.R.C.S. (Droitwich) in the Chair.

The **President** and Dr. **Bagshawe** (St. Leonard's) spoke of the great loss which had recently been sustained by the Society through the death of Dr. Symes Thompson and of Dr. Douglas Kerr (Bath) both of whom had been Presidents of the Society.

A paper was read by Dr. **Leonard Williams**, on the

TREATMENT OF GOUT BY THE INGESTION OF COMMON SALT-CONTAINING WATERS.

The author contended that Widal's work on the subject of common salt and its effect in cases of renal inadequacy should cause us to review the probable effects of common salt waters, which are given by the mouth in the treatment of gout. After a brief résumé of the salient points of Widal's work in reference to this question, he went on to say that inasmuch as gouty people were for the most part potentially inadequate in the matter of renal excretion, it seemed to him to be an unwise proceeding to continue to send gouty patients to salt water spas. He had made out a table showing the contents in common salt of some of the more popular spas, and he held that certain spas, notably in Germany, such as Kissingen, Homburg, and Wiesbaden, were unsuited to the treatment of gout when regarded from this point of view. He further expressed the opinion that inasmuch as the bowels were only accessory excretory organs where the products of nitrogenous metabolism were concerned, the wiser course was to advise gouty patients to those spas such as Contrexeville, Vittel, and more especially, Evian, whose waters were known to exercise a stimulating effect upon the kidneys, which constituted, after all, the normal physiological route for the discharge of nitrogenous waste.

The **President** remarked that simple waters, given in large quantities, and without sufficient intervals, do not give the diuretic effect produced by moderate quantities, and he believed this to be all the more true in cases of waters containing large quantities of sodium chloride. Therefore, it was necessary to watch carefully the action of the kidneys in treating gouty cases with saline waters. With due care in prescribing saline baths and waters an early increase in the flow of urine and a corresponding decrease in the gouty manifestations were usually found. There were no cases so hopeful as these which showed this early diuretic action.

Dr. **Solly** (Harrogate) said that whatever theoretical objection there might be to the use of salt-containing waters in gout, there was no doubt that the practical experience of a multitude, both of medical men and patients, went to prove that these waters were beneficial in gout. It was true that they must be administered with discretion, and with due regard to all ascertainable factors in the patient's case—of which the condition of the kidneys was very important. His own experience was that, leaving out acute cases, for which Harrogate waters were never recommended, all ordinary cases of gout were benefited by the strongest saline water of Harrogate, if only precautions were taken to secure from the first a thorough, though not drastic aperient action—this being often most satisfactorily obtained by a preliminary dose of euonymin or some other simple hepatic stimulant, and by the administration of sufficiently copious doses of the water.

Dr. A. P. **Luff** said that he could not agree that all gouty patients should be debarred from taking mineral waters containing sodium chloride. In those cases in which gross renal inadequacy existed it was right to forbid the use of such waters, but in other cases the waters were of great value to gouty patients as stimulants of hepatic metabolism.

Dr. C. W. **Buckley** (Buxton) considered it probable that the chloride radicle of common salt is of much importance in the therapeutic effect of these waters in gout, in view of the value of ammonium chloride, and also nitro-hydrochloric acid, in functional disorders of the liver. Hydrochloric acid has been used as a remedy for gout with success, a fact which also supports this view. He was quite in agreement with Dr. Luff that the kidneys were not the only organs to be considered, and that the function of common salt-containing waters was to act upon the liver, but held that any renal inadequacy contra-indicated them, no matter how slight it might be.

CORRESPONDENCE.

FROM OUR SPECIAL CORRESPONDENTS ABROAD.

FRANCE.

Paris Jan. 6th, 1907.

Biliary Cirrhosis.

From an anatomical and clinical point of view, two types of biliary cirrhosis are admitted by clinicians—biliary hypertrophic cirrhosis and biliary cirrhosis from obstruction by calculi.

Clearly isolated by Hanot in 1875, from the confused group of hypertrophic cirrhosis, biliary cirrhosis is essentially characterised by a considerable increase in volume of the liver, the spleen, chronic icterus, absence of ascites, and of complementary circulation.

Its cause is almost unknown. Alcoholism, paludism, syphilis, have been incriminated, but the affection seems to be somewhat hereditary. It is observed generally in young subjects of 25 to 35 years; it is more frequent in men, while children have been known to be affected.

The lesion consists in angiocholitis followed by peri-angiocholitis; the sclerosis invades the spaces, producing obliteration of the biliary ducts. The hepatic cells remain healthy, although hypertrophied, and do not undergo fatty degeneration, as in other forms of cirrhosis.

The liver and spleen are enormously increased in volume, in which also the abdominal ganglions participate.

As to the cause of the malady, only presumptions can be made. For Kiener, Hanot, Hayem, and Ascoli, the theory of general infection is considered sound. Chauffard believes in its splenic origin. According to him, the infection first attacks the spleen and the lymphatic ganglions, and secondly the liver.

The first symptoms of biliary cirrhosis are very obscure. The patient complains of *malaise*, inappetence, weight in the gastric region, flatulence after meals, tardy digestion. The patient loses flesh and strength, and sometimes epistaxis is observed.

Jaundice is sometimes the initial sign, appearing without any known cause or attributed to an access of grief, depressing emotions, alcoholic or alimentary excesses. The tongue is furred, and the hepatic region a little tender. With the usual treatment of rest, purgatives, and alkaline waters, the jaundice disappears, but returns in a short time; the liver becomes congested again, epistaxis and purpuric spots on the skin are observed and the patient gets weaker and weaker.

The jaundice is this time permanent, but varies in intensity from pale yellow to dark green. The urine is scanty and dark-coloured as with bile.

The liver is enormously enlarged, constituting with the icterus the fundamental symptom of the malady, completed, however, by the hypertrophy of the spleen. As negative symptoms may be mentioned absence of ascites and dilatation of the abdominal subcutaneous veins.

Repeated hæmorrhage is frequently observed as well as cutaneous purpura, itching, acne, &c. Towards the end œdema of the extremities sets in, with pulmonary congestion from cardiac insufficiency, and finally cachexia, to which the patient succumbs.

The duration of the affection may vary between several months and three or four years, according to the treatment and the resistance of the subject.

The prognosis is necessarily fatal, but some relief and extension of life may be obtained from treatment, which consists mainly in hygienic principles and régime.

The patient should avoid all alcoholic excess, all fatigue and overwork or mental strain. The lacto-vegetarian diet should alone be allowed, while antisepsis of the intestine will be realised by salol, salicilate of soda, or calomel in fractional doses; saline purgatives may be ordered periodically.

Biliary cirrhosis from obstruction by calculi differs from the former affection by the fact that the hepatic organ is atrophied. The biliary canals or ducts are greatly dilated from mechanical retention of the bile, which itself is modified and becomes a cause of irritation for the cells, which finally perish; atrophy of the organ is the result.

The symptoms consist in the presence of jaundice, varying in colour, and discoloration of the fæces; the urine contains biliary pigment, the patient complains of a distaste of fatty foods, of constipation, vomiting, itching, &c.

The diagnosis of biliary obstruction is very difficult, and even impossible if the history of the case does not reveal the existence of hepatic colic.

The treatment is purely surgical, and the only question to be studied is the best moment to operate. According to Schwartz, the operation should be done at the end of three or four months, especially if the patient is getting thin. Mongour believes that as long as the liver is able to defend itself nothing should be done; that medical treatment often succeeds. A liver subject to variations in form resists and defends itself for an indeterminate time; a liver, on the other hand, which remains definitely fixed in its dimensions (atrophy or hypertrophy) is a liver which has lost all functional adaptation, and places the life of the patient in immediate danger.

GERMANY.

Berlin, Jan 6th, 1907.

Typhoid Bacilli Carriers.

From work carried out in the Kaiserl. Gesundheitsanit we learn that during twenty-one months twenty-three carriers of typhoid bacilli were met with. Amongst the carriers were people ranging from sixty years of age down to one and a-half years. Out of the twenty-three cases a group of eleven was distinguished, inasmuch as no observable signs of illness of any kind were discoverable in its members. Seventeen hundred healthy individuals were examined during the period in which the investigation was being made, and the eleven were amongst this number. The period of bacilli excretion in this group was only of short duration. In contrast with the group of "acute" bacilli carriers was that of the "chronic" carriers. This group consisted of convalescents from typhoid fever, and in them the bacilli were met with in all stages after defervescence from six weeks up to eleven months. Some of the persons examined had had typhoid some years before, and occasionally examination revealed some bacilli in these. These latter cases have led to a belief that after the disease has run its course certain of the bacilli may continue a saprophytic existence in the gall bladder, and from there many find their way into the bowel. A definite disappearance of the bacilli in the chronic carrier was determined with certainty in one case only.

In practice it is of the highest importance to realise that typhoid bacilli may be excreted from healthy individuals, and that, passing into others they may set up typhoid fever; theoretically, such a thing might take place, although no actual observation of such an occurrence has yet been made. The so-called acute bacillus carrier, the writer, Dr. Klinger, thinks tolerably harmless, but the danger in the chronic cases is great so long as they are allowed out into the world, and especially when they themselves are ignorant of their condition and when they are uncleanly in their habits.

The rules for preventing mischief arising are cleansing of the anus and hands after every defæcation, and the strict forbidding of defæcation in unsuitable places Of course, disinfection of stools when the carrier is going about is not practicable, as supervision is impossible. Perhaps the discovery of some means of rapid evacuation of all bacilli when the disease has subsided will lead the way to greater security than the public have at present.

Milk and Typhoid.

From the same institution we have an instructive paper on this subject.

In Strassburg five people living in different streets in the same part of the town were attacked with typhoid fever one after the other. All had drunk milk uncooked from the same milkman. The milk came originally, as was proved, from two dairies of one village in the Landkreise Strassburg. Investigation showed that no one in the village was ill of the disease, but that about six months before a schoolboy had lain ill of cough, and that large quantities of typhoid bacilli had been present in his stools, and that it was possible that the water of a well adjoining or near to the privy had become contaminated.

In Strassburg also there were at another time eight cases of fever in different parts of the city, to which others were added some weeks later on. Each sufferer from the disease had drunk, as was proved, unboiled milk from the same milkhouse, which distributed only mixed milk from various dairies. More detailed examination showed, at one of the dairies from which the general supply was obtained, that a woman lived there who was apparently healthy, but whose stools contained typhoid bacilli.

The interesting cases were similar to a number observed by the writer, Dr. Kayser. During the years 1904 and 1905 two hundred and sixty cases of typhoid were observed in Strassburg, and in sixty of these a connection was discovered between the disease and the consumption of unboiled milk. The total percentage of cases then brought about of twenty-three was much increased in the latter year, when of one hundred and twenty-six cases this connection was discovered in fifty-one, *i.e.* forty per cent. Another interesting and striking fact was the number of servant girls who were affected, and also people employed in cooking in shops.

The moral of all this is that more exact supervision must be exercised in the case of all suspected persons, but herein lies a serious difficulty, as pointed out by Dr. Liebetieu, of Treves, in the *Zeitch. f. Med. Beambe*, November, 1906. The carriers of the bacilli and even the disseminators of the disease have not always been ill themselves; they cannot be classed as "ill," nor as "suspected of being ill," or of being "suspected of carrying infection." The disseminators of the disease have in many instances been in apparent perfect health, and there is no law in Germany or anywhere else that can get hold of such persons, dangerous as they certainly are. One cannot expect that the stools of all individuals shall be examined for typhoid bacilli, the most that can be done is to look carefully after all suspected individuals, and these will naturally be all engaged in some department of the milk trade, whether as milkers, washers out of pails and cans, or distributors. The matter is not a savoury one, but it must be faced. When a case of the disease is notified it will be the duty of the medical officer of health for the district to at once look up the milk supply that comes under suspicion, and then institute a searching inquiry into the constituents of the dejecta of all engaged in that particular supply of milk.

AUSTRIA.

Vienna, Jan. 6th, 1907.

Diuretic Medicines.

Löwi read a long paper to the Gesellschaft on the action of diuresis and the varied actions of the "Purin-derivatives" such as diuretin, caffein and digitalis. His opinion of the action of diuretin was that it increased the circulation of the vascular in the kidneys themselves, thus increasing blood changes, which was the opposite of digitalis, which increased the work of the heart by constricting the vessels.

There was an apparent anomaly in the action of digitalis which rendered explanation difficult. In a healthy individual no rise of pressure was observed, but if a morbid condition existed the blood pressure rose and produced a favourable result. Diuretin had also a beneficial effect on stenosis, which could not be attributed to the diuretic action where no œdema exists; we must therefore attribute this action to another property of the drug.

Schur was inclined to agree with Löwi on the action of diuretin in general, but when he tells us that it relieves pain in arterio-sclerosis he hesitated to believe it; neither was he supported by experiments, as none of them admitted, nor can it be demonstrated that dilatation of the vessel takes place under the action of diuretin.

Federn thought the congestion of the organ and increase of blood pressure was due to the peripheral irritation of the splanchnic nerve.

Braun thought that digitalis acted on the vascular system, and particularly on the central nervous system The increase of blood pressure plays a very insignificant part in arterio-sclerosis, which is contrary to the usual orthodox teaching.

Grossmann said the views put forward were quite contradictory, as we could not have excessive cardiac action and congestion as the true explanation. We have undeniable proof that increased cardiac pressure removes the congested state of the kidneys; we also know that digitalis has little or no effect on the healthy as a fact, but to speculate further is dangerous.

Bier's Congestion Treatment.

Eiselsberg gave a few examples of his method of applying Bier's treatment in acute inflammation. He has obtained wonderful results and speaks in high praise of this form of treatment. The chronic cases rapidly improve, the pain ceasing, and the natural secretions returning.

Bier's congestion treatment consists in checking or reducing the flow of blood through any inflamed part of the body.

Jerusalem showed several cases of phlegmonous lymphangitis which he had treated with the very best results by Bier's hyperæmic treatment. He showed three of "Bier-Klapp's" suction apparatus which he applied in the treatment of stiff joints.

Cystadenoma Mammæ.

Saar showed diagrams of this disease which might also be called mastitis chronica cystica. It was a genuine neoplasm arising from the epithelial cell, which forms the principal substance of the growth.

Trichonodosis.

Riehl showed a few cases of this disease, as well as preparation of others, that he had preserved. This is the trichorhexis nodosa of Kaposi, of which he concluded no ætiology could be given. Riehl now affirms that it is not a disease in the true sense, but is the outcome of mechanical irritation or neglect. Burning the hair or applying large quantities of fat are potent factors in the production of this anomalous condition.

Intestinal Infection.

The ideal disinfectant, according to Moro, is the regular changing of the contents of the bowel to allow of the active development of the normal bacteria. Feeding with the mother's milk is an excellent germicide for infants where the pathogenic type threatens to exist. In breast-fed children the bacillus bifidus is the mormal germ, which will attack and destroy every other pathogenic microbe present in the canal.

FROM OUR SPECIAL CORRESPONDENTS AT HOME.

SCOTLAND.

Health of Edinburgh during 1906.—The death rate during the year was 14.26 per 1,000. Of the 4,868 deaths, diseases of the chest accounted for 1,074, phthisis and other forms of tuberculosis for 611, and zymotic diseases 293, measles being the most fatal with 129. The births were 7,042, of which 617 were illegitimate; this gives a birth-rate of 24.41 per 1,000. During the year 2,147 cases were notified under the Infectious Diseases Act, comprising 987 scarlatina, 667 diphtheria, 337 erysipelas, 144 typhoid, 11 puerperal fever, and 1 relapsing fever. The admissions to the fever hospital were 3,079, the excess over the number of notifications being due to the number of cases of measles, etc., which are not scheduled for notification.

The Cost of Scottish Asylums.—The *Scotsman* of January 2nd gave prominence to a contributed article by an expert on this subject, which affords considerable food for reflection. The writer's text is Lord Rosebery's pronouncement at the opening of Bangour Asylum in which he dwelt on the enormous cost of erection and maintenance of asylums—"sepulchres for the living dead." From the article in question it seems that during the past half century the approximate cost for construction of asylums in Scotland has been four and a half millions, and the annual maintenance bill approximates to £450,000. Some of the Scottish asylums have been erected at a cost per head of £400, £500, and even £600—sums that would build villas for families of eight. What has contributed to this cost? Not the necessary heating, lighting and laundry plants, etc., nor the furnishings, nor the mural decorations, but the palatial masonry, the towers, domes, and minarets, the carving and sculpture, the massive wrought iron gates, the byres and piggeries befitting the palaces of millionaires, the parquet rout flooring, the tiled bathrooms, and the recreation rooms in their get up equal to any modern fashionable playhouse. These are not needed for the treatment of the 35 per cent. of curable cases, and are not justified for the housing of the 65 per cent. of chronic dements, chronic maniacs, inebriates, and epileptics who form the permanent pouplation of the asylum. The responsibility for this extravagance is variously laid on architects, and on local authorities, each anxious to go one better than its neighbour, yet there are Boards and architects who have shown how the thing can be done at less than half the cost. In the Kingseat Villa Asylum, Aberdeen, the cost has been £220 per patient, and at Ayr the erection of a hospital (the costliest part of an asylum) has been completed at £150 per bed. A table is given showing the annual cost of maintenance per patient, and the annual assessment per patient for buildings, lands, etc., in fifteen of the large asylums. The average is £28 for maintenance, £20 for assessment—a total of £48. Bangour Asylum heads the list with £37 10s. and £60 19s. respectively, while Ayr is at the foot with £26 and £6 16s. Woodilee, Glasgow, Midlothian, Lanark, Roxburgh, and Dundee, are near the average. In the year 1905, the amount of unpaid borrowed money for Scottish district asylums stood at £1,721,760, of which £199,000 stood to the debit of Gartloch, £195,300 to Govan, £183,400 to Lanark, £173,500 to Edinburgh, £122,690 to Aberdeen, and £91,000 to Dundee. Various remedies have been proposed for a state of matters loudly calling for reform. It has been proposed that Parish Councils, who provide all the patients and the entire maintenance bills, should have some say in administration. The Town Councils of Edinburgh and Glasgow already object to rate for institutions in the erection of which they have no say. A plan could easily be found to effect a combination of the three authorities—Town Council, Parish Council, and District Lunacy Board, which would be a step forward in local government.

Complimentary Dinner to Dr. Norman Walker.—Dr. Norman Walker was entertained to dinner at Kirkcaldy on December 28th, on the occasion of his election as direct representative for Scotland. The dinner was held under the auspices of the Fifeshire branch of the British Medical Association, and was presided over by Dr. Graham, Leven, who gave the toast of The Guest. The dinner was attended by a large company, many of whom came from a distance; a number of apologies from those who had been storm-stayed were read. The Lord Provost of Edinburgh, the Provost of Kirkcaldy, Mr. Munro Ferguson, M.P., and others were unavoidably prevented from being present.

BELFAST.

Public Health.—At a meeting of the Belfast Corporation held on New Year's Day, Dr. Bailie, the new Medical Officer of Health, made a brave show as a medical reformer. He is, of course, on his metal, and is naturally anxious to prove that he is better qualified for the post he holds than his professional brethren thought. He presented reports on the inspection of dairies, and on the prevention of tuberculosis, which were excellent as far as they went; but it remains to be seen whether he will have sufficient weight to enforce his reforms on the Corporation, which contains a solid body of property-owners and "property-developers" whose interests are strongly opposed to reforms. Meantime Dr. Bailie will no doubt be preparing his annual report, and we should like to remind him of some of the items for which we have looked in vain in his predecessor's reports for years back. We want some information as to inspection of dairies and slaughter-houses, inspection of meat and fish, milk, fruit, and vegetables. How many prosecutions were instituted, and how many convictions obtained? Typhoid and tuberculosis have received a fair amount of attention in recent reports; what about alcoholism and cancer? How are the female sanitary inspectors employed and what is the general result of their work? Is the refuse destructor working well or is it an expensive failure, only kept going to save some members of the Corporation from awkward questions as to why that particular make of destructor was chosen, and why the contractors were not kept up to the mark, before it was paid for? And, finally, if all these questions seem too trivial to Dr. Bailie, as they did to his predecessor, and he wants one worthy of a master mind, let him tell us a little about the main drainage of the city, whether it is working satisfactorily, and, if not, why not?

Case of Arsenical Poisoning at Antrim: Censure of Medical Man.—At an inquest held on January 4th, on the body of a farmer who died lately at Antrim, the evidence showed that there was a considerable quantity of arsenic present in the body. It was also proved that the deceased had made attempts to procure arsenic at several shops, and, having failed in these, finally got half an ounce of arsenic from Dr. Gawn, of Antrim, "for treating a horse." The arsenic was labelled "For external use only," and Dr. Gawn said that he did not charge for it, as he did not sell poisons or keep a poisons book. The jury returned a verdict of suicide from taking arsenic, adding that they were of the opinion that Dr. Gawn had been negligent in not visiting the deceased when told that he had taken some of the contents of the bottle. Dr. Gawn protested against the findings, and said that there was no evidence whatever that he had been told so, and that it was merely hearsay. As the evidence in question has not been published, it is impossible to express any opinion on it, but from various reports there is clearly a good deal of local feeling on the subject, and more may possibly be heard of it.

LETTERS TO THE EDITOR.

ANTI-VIVISECTION AND SPORT.

To the Editor of THE MEDICAL PRESS AND CIRCULAR.

SIR,—Will you allow me to say a word in reply to the letter signed "S." in your last issue. Your correspondent, referring to me, says "Can this Christian Minister not take the trouble to ascertain at first hand the facts about experiments upon animals, and in the meantime direct his further energies to the gross and unjustifiable forms of wholesale cruelty he rightly denounces?"

As regards the latter part of this question, the writer's suggestion is rather belated, inasmuch as I have devoted a great deal of my time, during the last fifteen years, to exposing and denouncing the horrors of "sport."

His advice is equally inapplicable to me on the subject of vivisection. My abomination of that practice is not founded on mere hearsay: I go, for my information, to accounts which the vivisectors themselves give of their proceedings. For instance, I take up Volume 46 of the "Transactions of the Pathological Society of London," and read at page 236 all about the kidney-slicing experiments on dogs, conducted by a well-known London doctor, and I rise from the perusal with the feeling that I had rather die a hundred deaths than blacken my soul by consenting that such deeds should be done for *my* benefit.

What I stand for is the demolition of cruelty in every sphere where it shows its hideous face.

I am, Sir, yours truly,
(Rev.) J. STRATTON.

Wokingham, January 7th.

To the Editor of THE MEDICAL PRESS AND CIRCULAR.

SIR,—From a communication to the *Field* of December 22nd, I see that Lord Ribblesdale has joined Mr. Peter Ormrod in establishing a pack of hounds to hunt deer in Lancashire and Yorks. These animals will be chased under conditions which will make the sport a cross between the carted-staghunt and the wild-deer-hunt of Exmoor. This is the plan suggested by the *Field* of September 3rd, 1892, in order to meet the possible fall of the Royal Buckhounds. Lord Ribblesdale, I presume, foreseeing the probable enactment of Mr. Luttrell's Spurious Sports Bill, which would make it illegal to hunt deer that have not had a month's freedom, is anxious to provide against the evil day, and so sets up a Hunt which he thinks the Bill would not touch.

All humanitarians, I am sure, will be extremely sorry that his lordship has taken this line. We live in times when education is rife, and one might legitimately expect that persons of position, instead of promoting a new form of sport, bearing more or less resemblance to the universally reprobated carted-deerhunt, would feel that the time has come for questioning the justifiability of hunting even really wild creatures.

I am, Sir, yours truly,
ONE OF THE PEOPLE.

December 29th, 1906.

OBITUARY.

FRANCIS ROBERTSON MACDONALD, M.D.EDIN., J.P.

THE death took place on January 2nd of Dr. F. Robertson MacDonald. He was a J.P. and an Hon. Sheriff-Substitute of Argyllshire. Dr. MacDonald went to Inverary about fifty years ago as a medical practitioner, and resigned his medical appointments to be medical attendant to the late Duchess of Argyll. On her death he was appointed private secretary to the late Duke, continuing in this office until the Duke's death. Deceased was a lineal descendant of the MacIans, Chiefs of Glencoe. He was proprietor of an estate in the neighbourhood of Aberdeen. His medical education was at Edinburgh University, where he took the degree of M.D. in 1853.

EDWARD ASHBY FARDON, L.R.C.P., M.R.C.S.Eng.

The death is announced of Mr. E. A. Fardon, who filled the post of resident medical officer of the Middlesex Hospital for a period of thirty years. The funeral took place at Ventnor on Saturday, and a memorial service was held on the same day in the chapel of the hospital with which he was so long connected. Mr. Fardon qualified in 1879, and after filling the junior resident post at the Middlesex Hospital, was appointed medical officer. His death will be regretted by many friends who knew him in that capacity.

THOMAS GEORGE O'SULLIVAN, L.R.C.P.LOND., L.R.C.S.I.

The announcement will be received with very deep regret of the death of Dr. T. G. O'Sullivan, Limerick, which occurred on the last day of 1906, after an illness of some months. Dr. O'Sullivan had been connected with many institutions in Limerick, and at one period took a large part in public life, and was elected mayor of the city in 1881. He was held in the highest esteem in Limerick, and was particularly appreciated by the poorer classes, to whose interest he devoted a large share of his professional ability. His medical education was received at the Carmichael School, Dublin, whence he qualified as L.R.C.P. of London in 1866.

BENJAMIN PITT JOHNSON, L.S.A.

We regret to announce the death of Dr. Benjamin Pitt Johnson, surgeon of the Cunard liner "Caronia," at the early age of 45. The sad event took place on Sunday at the Royal Infirmary. Dr. Johnson, during his sixteen years' service with the company, gained the esteem of the officers and crews of the various steamers in which he sailed, and many passengers who yearly travel between England and the States will regret to hear of his death. Dr. Johnson was a native of Ludlow, and was educated at Liverpool.

REVIEWS OF BOOKS.

ARTIFICIAL FEEDING AND FOOD DISORDERS. (a)

THE feeding of infants, though coæval with the beginning of the world, is evidently only a finite science. It has taken six editions (with six prefaces) to bring this work to its present pitch of perfection, the finishing touches having been given by a younger colleague who may be supposed to be "in the swim."

It is a regrettable fact that the information on the artificial alimentation of children so laboriously acquired is by no means of general knowledge, and many duly qualified men will be well advised to refresh their memories from time to time by a draught at the fountain head.

This standard treatise not only deals exhaustively with the artificial feeding of infants from a practical point of view with the authority begotten of extensive experience, but the reader is taken over the principal departures from health in infants dependent upon improper or inadequate alimentation.

The various categories of artificial foods are discussed, and analyses given of their alimentary values, the utility or otherwise of employing them being explained on a scientific basis. Altogether it will be seen that the joint work covers the whole ground, and it well maintains the authors' reputations.

(a) "Artificial Feeding and Food Disorders of Infants." By W. B. Cheadle, M.A., M.D.Cantab., F.R.C.S. Sixth Edition, edited by F. J. Poynton, M.D.Lond., F.R.C.S., Assistant Physician to University College Hospital, &c. London: Smith, Elder and Co. 1906. Price 5s.

WEEKLY SUMMARY OF MEDICAL LITERATURE, ENGLISH AND FOREIGN.

Specially compiled for THE MEDICAL PRESS AND CIRCULAR.

RECENT SURGICAL LITERATURE.

Case of Supplementary Lobe of the Liver causing Symptoms of Pyloric Obstruction.—Adams (*Glasgow Med. Journ.*, December, 1906) reports an operation undertaken by him with a view to relieving pyloric obstruction. The patient's emaciation and prostration were so marked that his intentions were directed more to palliative procedure rather than to radical measures. The history is as follows: The patient, a man of 28, suffered for eight years with pain in the stomach, followed by vomiting of blood. Liver dulness was normal. To the right of the middle line, midway between the xiphoid cartilage and the umbilicus, there was a thickening, but no definite tumour. There was no pain on palpation, succussion was unduly marked, and the patient was habitually constipated. Patient had lost a stone in weight during the three months before admission. The stomach was enlarged down to the umbilicus and 3½ inches to the right of the middle line. Patient complained of a dull pain over most of the epigastrium, and of another distinct pain of a stabbing character below the ribs 3 inches to the left of the middle line. On opening the abdomen a pedunculated lobe of the liver was found in such a position as to press on the pyloric end of the stomach. The lobule, which measured 3 inches by 2 inches, was covered by peritoneum, which was continuous with the broad, flat pedicle, the attachment of the latter being on the under surface of the liver to the left of the gall bladder. The pedicle of the abnormal lobe was ligatured prior to removal. The stomach revealed no thickening or tumour. No vomiting occurred after 24 hours, and the after history was uneventful. The author points out that even after investigation into the literature of the subject, it is difficult to know how a differential diagnosis could be made in this case prior to operation. But when the true nature of the case was recognised on opening the abdomen, the removal of the tumour was effected without much difficulty, and resulted in an absolute cessation of most of the symptoms. S.

Present Views on Diseases of the Joints.—Marsh (*Brit. Med. Journ.*, December 8th, 1906) classifies disease of joints into three groups. 1. Acute arthritis following wounds, or occurring in the course of acute infective osteomyelitis of pyæmia. 2. Arthritis following specific fevers, as acute rheumatism, typhoid, etc., the origin of which is usually obvious. 3. A group which is discussed somewhat fully, as the cases it includes are apt to lead to serious oversights and mistakes. It is composed of examples in which infection is produced by such everyday agents as streptococcus, staphylococcus, and gonococcus, but in which the symptoms differ so widely from those which we are in the habit of associating with these several infections, that the connection is apt to remain undetected. Taking the gonococcus, for instance. Arthritis developed in the course of an acute attack of gonorrhœa, the organism being of full virulence, produces the symptoms of an acute affection. But in a case of slight gleet of long standing, the joint infection by the gonococcus may present an entirely different picture. Such a case may bear a very close resemblance, from a clinical point of view, to tuberculous disease. The likeness is due to the fact that, under the influence of environment, the gonococcus has been deprived of so much of its original virulence, and is in such small quantities that the degree of irritation it produces is practically identical with that to which the Bacillus tuberculosis gives rise. The author cites several cases. In one case, a man aged 27 was admitted to hospital, and was believed to be suffering from tuberculous disease of the right knee, of five months' duration. All the symptoms fitted in exactly with this view. But it was ascertained that the patient had a very slight gleet, remaining after gonorrhœa contracted nine months previously. The urethral condition was set right by treatment, and in three months, under passive movement, massage, douching, and later, gradually increasing exercises, the knee completely recovered. The generalisation may be made that wherever, in any organ or any part of the body, a septic process exists, joint infection may result. The parts played by the tonsils and lymphatics of the pharynx in harbouring agents by which joints may be infected has only recently been fully appreciated. The author reports one or more cases in which the primary septic focus leading to joint disease was connected with each of the following conditions: (*a*) necrosed teeth, (*b*) septic cavities in the lungs, (*c*) empyema, (*d*) infective processes in the skin, (*e*) secondary to vaginal and uterine discharge (other than gonorrhœal). When the primary focus was cured in these cases, the arthritis disappeared, sometimes leaving an almost unimpaired joint, in other instances with resulting stiff joints. An obvious preliminary regarding treatment is that every effort must be used to find out the source of infection. The life history of the bacteria concerned must be remembered. The chief characteristic of the tubercle bacillus is its prolonged vitality and the manner in which it is able to resist destruction by phagocytes and kindred agencies. Streptococcus, staphylococcus, and gonococcus are much more easily eliminated by incision, drainage, disinfection, and phagocytosis. If arthritis is tuberculous, the joint must be kept for many months at complete rest, and the patient must, if possible, be treated on the open-air system; while in the other group the nurpose of treatment, when the supply of infective material has been cut off, will be the removal of coagulable lymph, the separation of adhesions, the restoration of movement, and the repair of atrophied muscles. These several results are best obtained by hot douching, massage, and often by manipulation under an anæsthetic. S.

On Sprains, and their Treatment.—Sir Wm. Bennett (*Brit. Med. Journ.*, December 8th, 1906) divides sprains into three classes. 1. Simple sprains, involving the soft parts only. 2. Sprains complicated by a fracture, the symptoms of the latter being so slight as to make it undiagnosable under ordinary circumstances, the symptoms of sprain being altogether predominant. 3. Sprains with gross nerve injury. In sprains without swelling, firm compression by strapping is most effectual in relieving pain. Massage cannot be commenced too soon, but passive movements are better deferred for six or seven days. Very hot fomentations are most serviceable when swelling is increasing after a sprain. This should be followed by pressure by means of a porous bandage. Slight voluntary movements cannot be commenced too soon. Massage should not be delayed more than twenty-four to thirty-six hours after the cessation of increase in local swelling. Passive movements should follow freely as soon as all heat has left the damaged part, whether the swelling be tense or not. In the case of sprain with fracture, the order of treatment should be massage, passive movement, voluntary movement. The reason for the early use of passive movement under these conditions is that, if the treatment is properly carried out, the detached piece of bone is not disturbed; whereas if voluntary movement were allowed, imperfect or faulty union would not improbably follow, with the usual imperfect recovery. The nerve injuries in sprains are of two kinds. In one, where the evidence of nerve lesion is pain along the line of distribution of the nerve, rest, and rest only, will bring about a complete and permanent cure. Massage does nothing but harm in the early stages of this type of case. In the other variety, numbness is the indication of nerve lesion. If this symptom has not disappeared in twenty-four hours, the only hope of cure lies in the skilful use of massage, supplemented after two or three days by galvanism. S.

The Surgical Treatment of Malignant Disease of the Stomach.—R. T. Morris (*Post Graduate*, December, 1906) gives his views on operating in cases of gastric carcinoma. They may be classified in the following way:—That operation for the removal of the stomach in cases of extensive malignant disease is almost never allowable; that operation for the relief of obstruction in cases where the disease is beyond the point of eradication is a questionable operation, that we may do on presenting the facts to the patient, and giving the patient a clear understanding of the condition. Some cases will get relief, but many will fail. We are seldom justified in operating for relief after the disease has gone beyond the point where eradication of the affection is possible. In those cases where the disease is limited to the pylorus, in the early stages where the diagnosis can be made, it is better to operate early, and without preliminary treatment, except for a very few days. As soon as we can make the diagnosis in these cases we should do the radical operation for eradication. G.

Isolated Omentum for Plastic Operations.—Girgolaff calls attention (*Zentralblatt für Chir.*, November 17, 1906) to the use of isolated portions of the great omentum for plastic work in abdominal operations. He finds that the stomach or large intestine may be experimentally injured, sutured loosely, and then covered over by a piece of omentum taken from the same animal. As a rule, within twenty-four hours the transplanted piece of omentum forms adhesions, containing blood-vessels, with the organ to which it was attached, and covers the wound perfectly, without forming any adhesions with the parietal peritonæum. The vitality of such isolated pieces of omentum is so great that the author has used them experimentally upon injuries of the liver as living tampons with excellent results. Numerous attempts have been made to implant omentum in a similar way upon the small intestine. The results obtained from this have not been so uniformly successful, and omentum cannot be considered quite trustworthy for this purpose. G.

Operation for Prolapsus Ani and Internal Piles.—D. Newman describes (*Lancet*, December 22nd, 1906) an operation he has devised for this affection. It consists in cauterising the mucous membrane of the rectum in six narrow strips from above downwards, each strip being four inches long by a quarter of an inch broad. This procedure is carried out by means of a special rectal speculum, whose sides being cut with long slits, allow the mucous membrane of the bowel to bulge through into the lumen of the speculum, where it is cauterised in the usual manner with the actual cautery. The following advantages are claimed for this operation:—1. The very sensitive area of the anus not being included in the operation, the patient suffers no shock, and little or no pain after the operation is over. 2. The cautery is applied while the mucous membrane and the muscular wall are as nearly as possible in their normal relationship. The adhesions which form are widespread, also, being in the form of longitudinal bands with uninjured mucous membrane between them, rather than as transverse rings, the danger of subsequent stricture is avoided. 3. The anus being uninjured, the sphincter acts normally at once after the operation. 4. In no case was there the slightest indication of sepsis after this operation; there was no case of suppression of urine, the after sickness was slight, and when the bowels were moved for the first time after the cauterisation, no great pain was suffered. 5. There has been no case of recurrence of prolapse or hæmorrhoids after this operation. G.

Pyelonephritis.—F. F. Smith (*New York Med. Jour.*, December 8th, 1906), recognising that in the large majority of cases pyelonephritis is an ascending affection from the urinary bladder, calls special attention to the ætiology of inflammation of the bladder, and draws the following conclusions as the result of an elaborate bacteriological study. 1. Every cystitis is due to microbes, with the rare exception of cases caused by chemical irritation. 2. Ordinarily we find one pure culture in enormous quantities. 3. The bacillus most frequently found, and described by other authors under different names, is identical with the ordinary intestinal parasite, the bacterium coli communis; it is pyogenic and infectious, of very variable virulence. 4. In the urethra and prepuce of males, and in the vagina of females, are frequently found these pathogenic bacteria which, introduced into the bladder, can provoke a cystitis. 5. The microbe alone does not produce cystitis, except in certain cases where the proteus vulgaris is present, which is a determining cause by virtue of its decomposing action in connection with urea. 6. The microbe does not cause cystitis until the bladder has been rendered vulnerable by the influence of certain predisposing agents, like retention and traumatism. 7. Retention or traumatism alone are insufficient; a microbe is always the cause. 8. In every cystitis pus will be found in varying quantities; the existence of a catarrhal cystitis is very doubtful. G.

Congenital Word Blindness.—S. Stephenson (*British Journal of Child. Disease*, 1905) writes on this subject, which has been becoming more familiar of recent years, although the reported cases are few. Yet he believes there are good reasons for supposing that it is far from uncommon among the children of the lower classes. From the nature of the cases most of them are met by ophthalmic surgeons in the first instance. An otherwise intelligent child experiences difficulty in learning how to read, although numbers present little trouble. A child who cannot learn how to read "dog" will quickly solve small arithmetical sums. It is thought that the condition is probably due to a congenital defect in the visual memory centre for words and letters. Most of the patients would appear to have their auditory memory highly developed. A patient of Hinshelwood concealed his difficulty in reading by learning his book off by heart. The other centres seem to compensate for the loss of the visual memory, for patients can help themselves by repeating sentences with the lips or tracing the words with their finger. Some of the cases had a parent who never learnt how to read. M.

Chronic Aural Discharges.—F. C. Hotz (*Ann. Ot., Rhin. and Laryngology*, December, 1905) considers that these cases do not receive sufficient personal attention from the surgeon; that there is too much indiscriminate ordering of lotions and drops for the patient to use at home, which do little more than cleanse the meatus, and fail to reach the causes of the discharge, which may be so various. After a lengthened period of this home treatment, perhaps carried out most conscientiously, the discharge continues, and the patient is advised and submitted to a "radical" operation. Hotz maintains that with a limited number of instruments, patience, and amount of time many of these cases can be cured. He uses probes, applicators, and curettes with flexible stems, so that they may be curved to suit the necessities of each case. With these inspissated masses, granulations, polypi, carious or necrosed spots can be reached and scraped, débris being removed by an attic syringe. Granulations and small polypi can be removed by repeated applications of chromic acid. After an apparent cure Hotz recommends that the case should be re-examined at intervals of several weeks to see if the cavity keeps clean and dry and free from smell. M.

MEDICAL NEWS IN BRIEF.

Government Stamps on Patent Medicines.—Coroner's Strong Remarks.

Dr. Frederick J. Waldo, the Southwark Coroner, held an inquest on January 1st with reference to the death of Alfred A. Cushing, aged 42 years, an engineer's labourer. The widow said that her husband used to doctor himself, as he said doctors did him no good. The Coroner: What did he take? The Witness: Anything he was told, and he also used an inhaler for the nose. Continuing, she said that on Friday she found him ill, and she sent for a doctor, who pronounced him dead. He had not previously seen a medical man for twelve months.

Dr. Paton testified death was due to consumption. He produced a pamphlet relating to the inhaler used by Cushing, an instrument for which the widow said he paid £3 3s., in addition to 8s. an ounce for the fluid to be used with it.

The Coroner (examining it): It is recommended for asthma, hay fever, and catarrh, and I see "Ohio. U.S.A.," on it. Did it give relief?

The Widow: He reckoned it did.

The Coroner: I have had a number of cases of quack medicines in connection with which credulous people are deceived by seeing the Government proprietary article stamp on them, and are deluded into believing that the Government guarantee the contents. They get a rich harvest out of the sale of the stamps, but I think the sooner the Government do away with the stamps the better. so that the public may be undeceived. What does this fluid consist of?

The Doctor: I have no idea, but I presume it is some harmless liquid. These things usually are.

The Coroner: Then that must be a fraud on the public if it is of no service, though harmless.

Dr. Paton: I know this, that it is a good stroke of business, for while they charge £3 3s. for the inhaler and 8s. an ounce for the fluid, the whole lot could be got for 3s. or 4s.

The Coroner: Can you say if the using of this hastened the man's death?

Dr. Paton: I am not prepared to speak as to that, as the man had been using it for a long time, and was in an advanced state of consumption.

The Coroner: Under the circumstances nothing can be done, as we do not know whether this was harmless or not.

The jury returned a verdict of death from natural causes.

Medical Training for Missionaries.

The Committee of Livingstone College, in their recent annual report, announce that a similar school of medical training for missionaries is about to be established in Germany. This is the result of a visit paid to Great Britain by Herr Oberlehrer Kammerer, Secretary of the Stuttgart Medical Missionary Association, who carefully investigated the work of Livingstone College and of the London and Edinburgh Medical Missionary Societies, and who on his return called a conference of the chief German and German-Swiss missionary societies, and laid before them the plan of an institute both for the training of medical missionaries and for the instruction of ordinary missionaries in the elements of medicine and surgery. Livingstone College has now been at work for 13 years. Before that time young missionaries who wanted a little of the medical knowledge that practically all their fraternity need, had to pick up information as best they could at the general hospitals, chiefly in the out-patients' departments, without any systematic lectures or any preliminary training in anatomy and physiology. Careful steps are taken to prevent the Livingstone College students from attempting to treat cases which are clearly beyond their powers, or competing with fully-qualified practitioners. During the past year 24 students—Anglican, Congregationalist, Methodist, Moravian, French Protestant, and of other denominations—have been trained at the college. The accounts show a deficit of £522, in addition to a mortgage of £3,500 on the college property at Leyton; but the Committee chiefly desire to increase the number of students, whose fees would largely meet the financial need.

Slaughter of Tuberculous Pigs.

IN the House of Commons on the 12th inst., Mr. Ffrench asked the President of the Local Government Board whether he is aware that the value of pigs seized and destroyed weekly in Birmingham for tuberculosis has been estimated at £100, and that it has been admitted by the Town Clerk of Birmingham that the approximate value of pigs destroyed each week for the four weeks ended November 17 was £31 18s.; and whether he will take steps to have those dealers recompensed whose pigs have been destroyed in the interest of the public. Mr. Burns said he was not aware of any authority for the first statement. Its accuracy was denied by the Town Clerk on behalf of the Corporation. He was informed that the value of pigs destroyed for the four weeks ended November 17 was as stated, but that the number was considerably above the average of the year. He had no authority to cause the dealers to be recompensed. Mr. Ffrench: Are not these pigs slaughtered in Birmingham inspected, and passed free of disease, by your inspectors? What are the special qualifications of the Birmingham inspectors which enable them to discover tuberculosis more than the Government inspector? Mr. Burns did not doubt the qualifications of the Birmingham inspectors to discharge their duties thoroughly. (Cheers.)—Mr. Will Thorne: Can the right hon. gentleman say what becomes of the condemned pigs? (Laughter).—Mr. Burns: I hope by means of a Bill I have before the House to ensure that these pigs are not sold as food for human consumption. (Cheers.)

Medical Sickness and Accident Society.

THE usual monthly meeting of the Executive Committee of the Medical Sickness, Annuity, and Life Assurance Society, was held on the 28th ult. There were present Dr. de Havilland-Hall, in the Chair; Dr. J. Brindley James, Dr. W. Knowsley Sibley, Mr. F. Swinford Edwards, Dr. F. J. Allan, Dr. St. Clair B. Shadwell, Mr. H. P. Symonds, Dr. Fredk. S. Palmer, and Dr. J. B. Ball. The accounts presented to the Committee showed that the business of the society was satisfactorily progressing, although the large number of influenza claims received during the last few weeks will make the margin in favour of the funds somewhat smaller than was anticipated. A considerable number of members are now on the half-pay list, and this practically permanent provision for those who cannot again perform professional work is looked upon as one of the most useful features of the society's operations.

BELGIAN PARLIAMENTARY GROUP.—The medical members of the Belgian Parliament have, in a petition addressed to the Minister of the Interior and of Public Instruction, asked him to consider the expediency of creating a clinic of dentistry in each of the State Universities. They express the opinion that such a step is desirable. The Minister has agreed to look into the matter. The Parliamentary Group has further decided to press forward as much as possible the debate on the proposed law on the practice of medicine, and that on compulsory vaccination.

NOTICES TO CORRESPONDENTS, &c.

☞ **Correspondents** requiring a reply in this column are particularly requested to make use of a *Distinctive Signature or Initial*, and to avoid the practice of signing themselves "Reader," "Subscriber," "Old Subscriber," &c. Much confusion will be spared by attention to this rule.

Reprints.—Reprints of articles appearing in this journal can be had at a reduced rate, providing authors give notice to the Publisher or Printer before the type has been distributed. This should be done when returning proofs.

Contributors are kindly requested to send their communications, if resident in England or the Colonies, to the Editor at the London office; if resident in Ireland, to the Dublin office, in order to save time in reforwarding from office to office. When sending subscriptions, the same rule applies as to office; these should be addressed to the Publisher.

Original Articles or Letters intended for publication should be written on one side of the paper only, and must be authenticated with the name and address of the writer, not necessarily for publication but as evidence of identity.

SUBSCRIPTIONS.

Subscriptions may commence at any date, but the two volumes each year begin on January 1st and July 1st respectively. Terms per annum, 21s.; post free at home or abroad. Foreign subscriptions must be paid in advance.

POPE AND DOCTOR.

Our Rome Correspondent writes: "The Momento" of Turin tells the following tale about Leo XIII. and the lately-deceased Dr. Lapponi. The Holy Father was about to give a long and important audience to some pilgrims, although he had a very bad cold Lapponi carefully provided the Pope with a box of pastilles, begging him to take one from time to time. The doctor then took his place in the audience chamber in a corner from which he would be able to catch the Pope's eye.

After he had spoken for some time Leo XIII. became very hoarse, but the doctor noticed that he did not take the pastilles. To attract the Pope's attention Lapponi coughed loudly. The Pope looked up, and then said to an attendant, "Call the doctor." Naturally there was some alarm among the bystanders, who thought the Pontiff felt ill. But as Lapponi approached, Leo XIII. drew the box of pastilles from his pocket, and holding it out to him said: "Doctor, we heard you cough. Will you take one."—*Tribune.*

Xeres.—The first attempt to use the abdominal route for hysterectomy for cancer was made as long ago as 1878 by Freund. Wertheim's work, published in 1900 and 1901, will give the facts required.

Dr. L.—After forcible delivery rupture of the liver does occur, and not very infrequently.

Fibroma.—We cannot recommend the institution named. It may be properly conducted, but it is not under any definite medical supervision. You would be wise not to patronise it without very careful enquiry.

A DOCTOR'S "DIPLOMACIES."

At the annual meeting of the Flint Female Friendly Society last week Mr. W. A. F. Twemlow, M.R.C.S.Eng., and L.R.C.P.Lond., who has recently commenced practice in Flint, was, with one exception, unanimously elected to be medical officer. An objector proposed that the election be deferred for a month, in order that the doctor might show his "diplomacies."

L. R. M.—The preparation has rather a misleading name. It is not an anæsthetic proper, but rather a drug to paralyse the nerve terminals in the stomach, and has been used to check or prevent vomiting.

Scrutator.—You do not say if you have sent your account to the address stated. The gentleman you name is well-known at the institution mentioned; at least he held the appointment there at one time to our own knowledge. If no reply is returned to your letter, a *closed* note to him addressed care of the Secretary would be almost sure to be forwarded.

Meetings of the Societies, Lectures, &c.

Wednesday, January 9th.

Dermatological Society of London (11 Chandos Street, Cavendish Square, W.).—5.15 p.m.: Meeting.

Hunterian Society (St. Bartholomew's Hospital).—4 p.m.: Clinical Afternoon.

Medical Graduates' College and Polyclinic (22 Chenies Street, W.C.).—4 p.m.: Mr. J. Clarke: Clinique. (Surgical). 5.15 p.m.: Lecture:—Dr. H. Campbell: The Rôle of Blood Pressure in Disease.

North-East London Post-Graduate College (Tottenham Hospital, N.).—2.30 p.m.: Cliniques:—Dermatological (Dr. Meachen), Ophthalmological (Mr. Brooks), Medical (Dr. Whipham).

Thursday, January 10th.

British Gynæcological Society (20 Hanover Square, W.).—8 p.m.: Annual General Meeting. Valedictory Address: The President.

Medical Graduates' College and Polyclinic (22 Chenies Street, W.C.).—4 p.m.: Mr. Hutchinson: Clinique. (Surgical). 5.15 p.m.: Lecture:—Mr. M. Yearsley: General Disease in Relation to the Ear.

North-East London Post-Graduate College (Tottenham Hospital, N.).—2.30 p.m.: Cliniques:—Gynæcological (Dr. Giles), Medical (Dr. Whiting), Surgical (Mr. Carson). 3 p.m.: Clinique:—Medical In-patient (Dr. Chappel). 4.30 p.m. Lecture:—Mr. H. W. Carson: Peritonitis, its Pathology, Diagnosis, and Treatment.

Friday, January 11th.

Wimbledon and District Medical Society (Worple Hall, Worple Road, Wimbledon).—9 p.m.: Clinical Evening.

Clinical Society of London (20 Hanover Square, W.)—8.30 p.m.: Papers:—Dr. F. H. Hawkins: A Case of Acute Pneumonia with Abscess of the Lung and Acute Endocarditis. Dr. Forsyth: A Fatal Case of Myxœdema with Changes in the Parathyroid. Dr. Langmead (introduced by Dr. Garrod): The Association of Tetany with Dilatation of the Large Intestine.

Medical Graduates' College and Polyclinic (22 Chenies Street, W.C.).—4 p.m.: Mr. W. Stuart-Low: Clinique. (Ear.)

Vacancies.

Newport Borough Asylum, Caerleon, Mon.—Assistant Medical Officer. Salary £125 per annum, with board, apartments, and attendance. Applications to the Medical Superintendent.

Bath Royal United Hospital.—Resident Medical Officer. Salary £100 per annum, with board, lodging, and washing. Applications to J. M. Sheppard, F.C.I.S., Secretary

Liverpool Dispensaries.—Head Surgeon. Salary £200 per annum, with board and apartments. Applications to K. Stretch, Auditor, 56 Vauxhall-road, Liverpool.

Liverpool Dispensaries.—Assistant Surgeon. Salary £100 per annum, with board and apartments. Applications to K. Stretch, Auditor, 56 Vauxhall Road, Liverpool.

Royal National Hospital for Consumption. Ventnor.—Senior Resident Medical Officer. Salary £200 per annum, with board and lodging. Applications to the Secretary, 34 Craven Street, Charing Cross, London.

Stroud General Hospital.—House Surgeon. Salary £100 per annum, with board, lodging, and washing. Applications to the Hon. Secretary.

London Open-Air Sanatorium, Linewood, Wokingham, Berks.—Assistant Medical Officer. Salary £100 per annum, all found. Applications to the Medical Superintendent.

Carmarthen, Cardigan, and Pembroke Joint Counties Lunatic Asylum, Carmarthen.—Junior Assistant Medical Officer. Salary £150 per annum, with furnished rooms, board, washing, and attendance. Applications to W. Morgan Griffiths, Clerk to the Asylum Visitors, Carmarthen.

Royal South Hants and Southampton Hospital.—House Physician. Salary £100 per annum, with rooms, board, and washing. Applications to T. A. Fisher Hall, Secretary.

Down District Asylum, Downpatrick.—Junior Assistant Medical Officer. Salary £130 per annum, with board, residence, and laundry. Applications to M. J. Nolan, Resident Medical Superintendent.

Appointments.

Champtaloup, Sydney T., M.B., Ch.B., House Surgeon at the Cardiff Infirmary.

Coates, Charles Joseph Adams, L.R.C.P. and S.Edin., L.F.P.S. Glasg., Medical Officer for the Fourth District by the Shepton Mallett (Somerset) Board of Guardians.

Finch, Alexander Henry, L.R.C.P.Lond., M.R.C.S., Public Vaccinator for the First District by the Shepton Mallet (Somerset) Board of Guardians.

Kynoch, J. A. C., M.B., F.R.C.P., F.R.C.S.Edin., Extern Examiner in Midwifery at the University of Durham.

MacKinnon, Murdoch, M.B., Ch.B.Edin., House Surgeon at the Cardiff Infirmary.

Sheppard, Amy, M.B.Lond., D.P.H.Camb., Ophthalmic Surgeon to the Canning Town Hospital.

Watkins, William Richard Spencer, M.B., Ch.B.Edin., Resident Medical Officer at the Cardiff Infirmary.

Watson, G. W., M.D.Lond., M.R.C.P.Lond., Pathologist to the Leeds Public Dispensary and Honorary Assistant Physician to the Association for the Prevention and Cure of Tuberculosis.

Births.

Carpenter.—On Jan. 3rd, at St. John's House, Blackheath, the wife of Sidney M. Carpenter, L.D.S., R.C.S.Eng. (and of 62 Queen Anne Street, London), of a daughter.

Hutcheson.—On Dec. 14, at Bijnor, United Provinces, India, the wife of Captain G. Hutcheson, Indian Medical Service, of a son.

Steel.—On Jan. 2nd, at Stirling House, Alexandra Road, South Farnborough, Hants, the wife of Major E. B. Steel, R.A.M.C., of a son.

Marriages.

Dittmar—Wilkins.—On Jan. 2nd, at Hartley Witney Church, Winchfield, Hants, Frederick Dittmar, M.A., M.D., D.P.H., Medical Inspector to the Local Government Board for Scotland, eldest son of the late Professor Dittmar, LL.D., F.R.S., to Catherine Beatrice Wilkins, M.A.Lond., of St. Hilary's, Winchfield, Hants, daughter of Thomas Wilkins, of Cheltenham.

Gilchrist—Osmond.—On Jan. 5th, at St. James's Church, Weybridge, James Gilchrist, M.A., M.D., Ch.B., Farnboro House, Sydenham, to Constance Lilian, youngest daughter of the late James Osmond and of Mrs. Osmond, Casita, Weybridge.

Scott—Jelf-Reveley.—On Jan. 3rd, at St. John's Church, Torquay, Herbert Bodley Scott, I.M.S., son of Mr. and Mrs. Scott, Aldington, Bournemouth, to Sybil Claudia Jane, eldest daughter of Mr. and Mrs. E. P. Jelf-Reveley, of Brynygwinucha, Dolgelley.

Deaths.

Austin-Robinson.—On Jan. 3rd, at Hastings, of acute meningitis, Gwenllian Rogers (Gwenylw), aged four years, only daughter of the late Frederic Austin-Robinson, M.R.C.S.Eng., L.R.C.P.Lond., of Nottingham Road, Natal.

Tuke.—On Jan. 5th, at Chiswick House, Chiswick, Sophia Jane Tuke, widow of the late T. Harrington Tuke, M.D., F.R.C.P., and daughter of the late John Conolly, M.D., F.R.C.P., aged 82.

THE MEDICAL PRESS AND CIRCULAR.

"SALUS POPULI SUPREMA LEX."

VOL. CXXXIV. WEDNESDAY, JANUARY 16, 1907. No. 3

NOTES AND COMMENTS.

Surgical Resurrection.

THINGS are apt to be a little dull and stagnant after the excitements of Christmas and New Year, but this has not been the case during the first few weeks of 1907. The usual monotony has been staved off by a number of wonderful achievements in surgery, which have been unearthed by the ubiquitous reporter ere ever they had the chance of finding their way into the recognised organs of the profession. For instance, there is the case which is described by several papers under such lurid headings as "Farnham Hospital Miracle," "Child Raised from the Dead," "Snatched from Death," and so on. Happily, the names of the medical men concerned in this latter-day miracle are not given, and the circumstances seem to have been related by some inexperienced underling to whom they presented all the elements of novelty and surprise. The child who was so sensationally resurrected, it appears, was taken to the hospital in a condition of partial asphyxia from laryngeal diphtheria, and was, of course, promptly subjected to tracheotomy by the medical man in attendance. By the aid of artificial respiration, strychnine and brandy injections, and other routine measures, breathing, which had been in abeyance, was resumed, and the child gradually came round. Such a result is very satisfactory, but fortunately it is by no means unusual, as every house-surgeon in the country can testify. The ignorance of people with regard to commonplace surgical "miracles" is pathetic, but the stuff on which they are fed is rather more miraculous than the "miracles" themselves.

Further Marvels.

OTHER marvellous triumphs recently announced in leading daily newspapers are "Transplanting an Eye" and "Possibility of a Severed Head being Replaced." The former of these feats is whittled down to very small dimensions when one comes to look into it; in fact, the "cure" consisted in certain grafts of the "cornea lobe" of an eye removed from one patient being placed in the defective "cornea lobe" of another. The cure was far from successful in one eye, as the grafts caused painful swelling, and had to be removed, but in the other eye they are said to have taken. The size of the grafts is not mentioned. But if we pass from this anti-climax to the "severed head" we find that this yet-to-be event is only one of a "perspective of possibilities . . . enough to make one dizzy." We fancy that any "perspective of possibilities" is calculated to have that effect, except perhaps in the case of one whose head had been severed. It is highly probable that he would be unable to feel dizzy again, even with the recently detached member fixed on his shoulders *secundem artem.*

Faith and Strychnine.

THERE is, we all know, a faith that removes mountains, but there is also a faith, so we are assured, that is prepared to swallow strychnine. The latter quality animates the Rev. Staple Desmones, who, it need hardly be added, lives, moves, and has his being in the U.S.A. But let us not be uncharitable to Mr. Desmones, for the faith that promotes the strychnine-swallowing proposal is faith in the medical faculty, and he is prepared to drink *liquor strychninæ* against any Christian Scientist, he himself to be treated by an ethically-practising physician, while his opponent is to be left to the tender mercies of the Eddyites. Of the legality of this proceeding we are not quite satisfied, for in the eye of the English law it is a crime to compass the death of a fellow-creature, but in America there may be more freedom, and a man may, for aught we know, be allowed to incite another to swallow strychnine if he thinks it will serve a good purpose. But we can hardly advise Mr. Staple Desmones to rely too exclusively on the medical art, for it has yet to discover a trustworthy antidote for strychnine-poisoning. If he would oblige by swallowing half-a-crown, we might attempt to recover it with better promise of success.

Medicine and Sex.

PROFESSOR VON BERGMANN, at the recent celebration of his seventieth birthday, let himself go a little and gave his views on many professional questions of the day. To the Editor of *Medicin für Alle*—a rather curious paper to choose for the purpose—he has explained that he is decidedly against women studying medicine, "for," said he, "they are neither physically nor mentally capable of it." If, he argued, they have shown themselves unable to retain the monopolies of cooking and sewing, which once were theirs, how can they compete with male doctors? "Were it possible to obliterate sex distinctions, women might become good doctors, but that is not to be thought of." Few will be disposed to disagree with the distinguished surgeon when he says that the obliteration of sex distinctions is not to be thought of; it would be something of a waste of time to indulge in such speculations until biological science is considerably more advanced than it is at the present day. Perhaps some unborn Mendel may arise to teach us how to divine the aptitudes of the embryo for the career of medicine or for public life, and how to shape its sex accordingly. Till then let us suffer suffragettes gladly.

Medicine and Marriage.

SUCH in effect would seem the view of Professor Lassar, who in the *Frauen Zeitung* vigorously combats the view that women are not worthy to sacrifice in the temple of Hippocrates. They have proved themselves capable of practising medicine with credit in England, Russia, America, India, and—of all places—Bosnia, says that authority, and why not therefore in Germany? Because, he avers, German women have so long toiled in bondage to the male that they cannot at a moment's notice rise to the "immeasurably higher level dedicated to science." It will be news to most people, it certainly is to us, that the German frau is inferior in intellectual culture to the ladies of Bosnia, but perhaps if the masculine fetters are removed, she too may rise to their immeasurably higher level, and leave her husband grumping for his dinner. That is, if she is to have a husband at all, for Professor Lassar asks "To whom would it occur to let his mind occupy itself with personal thoughts of a base kind in the serious atmosphere of a university hall or in a hospital ward? Who would think, while working for the betterment of the sick patient, of sex distinctions?" We might be suspected of a pun of a base kind if we suggested that Professor Lassar was "laying it on thick," but how little can he know of the gallantries of Anglo-Saxon medical co-education where the base thought of marriage engendered in the Outpatients or by the sick bed is brought to fruition under the most regular ecclesiastical auspices, with a repetition that has grown almost monotonous!

'Liza and the Students.

ONE argument the co-educationalists are fond of using is that the gentle feminine would smooth down the rude, uncouth young medical male. But does he really need such influence? Has not the medical student of the day reacted too far from the Bob Sawyer ideal, and would he not be somewhat better for a little admixture of that gentleman's knowledge of the world and of human nature? Thoughts such as these are suggested by the perusal of the account of an inquest held last week on a Lambeth infant. The mother, it would appear, had engaged the services of charity for help in her confinement, and was supplied at the appropriate time with two medical students. Whether through gratitude for the help thus afforded, or through spontaneous attachment to the young gentlemen, or merely through following the picturesque habit of Lambeth, the labouring mother and her "lidy friend" persisted, much to the annoyance of the youths, in calling them "old dear," and "old darling." Now this would have suited Bob Sawyer to the ground, and he would probably have retorted by calling the ladies "mother," and "auntie." Not so the modern product of the aseptic theatre and the bacteriological laboratory. The medical students pointed out the grave indecorum of the ladies' behaviour, and announced that they could not consent to be made the subjects of such indignities. But the 'Lizas of Lambeth are not easily snubbed, and these ladies continuing the affectionate attentions, the gentlemen left the case. No further medical assistance was sought, and the child died a few hours after birth of some accidental cause.

LEADING ARTICLE.

THE EDALJI CASE.

THE notorious case of Mr. Edalji has been brought once again pointedly before the attention of the public. This time the challenge has been made in the *Daily Telegraph* by Sir A. Conan Doyle. In two long articles published on the 11th and 12th of the current month, he deals exhaustively with the whole case in his usual clever, concise, and powerful manner. One of his strongest grounds may be attributed to his early medical experiences, when, it is matter of common knowledge, he was specially interested in the study of diseases of the eye. With that part of his argument we shall deal later. As regards the main portion of this most interesting document we are in complete accord. Our readers for 1903 need not be reminded that in that year we drew up a petition to the then Home Secretary, Mr. Akers-Douglas. The nature of our views may be gathered from a special editorial notice in our issue of November 11th, 1903, under the title of "The Wyrley Cattle Maiming Outrage." "We feel it a public duty," the notice ran, "to call urgent attention to the cattle maiming case at Wyrley. A young Birmingham solicitor lies in prison condemned to penal servitude as the perpetrator of a number of senseless and absolutely brutal and wanton outrages on cattle. The evidence on which he has been convicted was purely circumstantial, and, as such, open to the fallacies that must necessarily accompany that class of evidence. During his imprisonment, and while awaiting trial, a further cattle maiming outrage was committed at Wyrley, the village where accused lived. Since his conviction still other cattle have been maimed and killed. On this ground alone, therefore, we submit that his sentence demands revision. But if an educated solicitor killed cattle in the senseless and purposeless manner under which the Wyrley outrages were comitted, we submit, unhesitatingly, that he was, on conviction, fitted for a lunatic asylum rather than a prison. There has been a grave miscarriage of justice, and we appeal to the Home Office for immediate action by way of revision of the sentence in this case. If necessary, we are prepared to nominate the necessary scientific body of investigation as to the state of mind of a cattle maimer of the kind involved in the assumption of the recent sentence." This petition was signed by many medical men, including such eminent authorities on mental disease as Dr. Savage, Professor Clouston, Dr. Bevan Lewis, Dr. Younger, and by such prominent men as Dr. F. J. Waldo, Dr. Ward Cousins, Dr. F. J. Smith, Dr. Danford Thomas, Dr. H. Jellett, and Mr. E. H. Tweedy. The petition was formally acknowledged by the Home Secretary, but no official reference has been since made as to any official investigation of the state of mind of Edalji. From time to time we have referred to the case of this unhappy man. In February, 1905, we noticed the review of the affair published by *Truth*, and joined in the emphatic demand that it should be reinvestigated. We then said: "It is difficult to escape the conclusion that either Mr. Edalji is an innocent man, as the continuance of the outrages after his imprisonment suggests, or that he is a poor madman who should be cared for in an asylum." Since then a new Home Secretary, Mr. Herbert Gladstone, has appeared upon the scene, and a few months ago Mr. Edalji was released. That event means presumably that his innocence was at length officially recognised. Now comes the demand from many parts of the country that he should be given a free pardon—that formal warrant of innocence which is ironically granted by the Crown in the case of subjects convicted of offences they have not committed. It is to be hoped that this timely act of grace will be performed in order to minimise as far as possible the far-reaching moral disturbances arising from so palpable a miscarriage of justice. One point insisted upon by Sir Conan Doyle is that owing to the physical defect of vision created by severe astigmatism, Mr. Edalji was physically unable to roam about at night, and cover the distance requisite to encompass the evil deeds of which he was found guilty. The argument is so highly technical that it is hardly possible to deal with it off-hand on general grounds. We have accordingly referred it to Mr. Sydney Stephenson, the editor of the *Ophthalmoscope*, whose remarks will be found following the present article. We may perhaps venture to make a slight criticism upon Sir Conan Doyle's challenge to any police constable to cover the same ground at night within the requisite period of time if provided with spectacles made so as to astigmatise his vision to a degree corresponding to that of Mr. Edalji's. It seems to us fairly evident that the conditions of experiment would not be identical enough to warrant sound conclusions therefrom. In the one case we have a man who has had his astigmatism from birth, and who has learned to interpret more or less correctly the distorted world in which he lives; while in the other the constable is plunged suddenly into a topsy-turvey environment. But, apart from that particular theory, Sir Conan Doyle has presented the world with a convincing case of the innocence of Mr. Edalji. We welcome his contribution, not only as coming from a medical man, but also as a vindication of the strong attitude taken up from the first by the Medical Press and Circular. It has always seemed to us that the public must look to the medical profession for much of the future advance in criminal law reform, of which so much has been heard of late years. We hope in the course of a few days or weeks to be able to announce a free pardon from the King for one whom we cannot but regard as the hapless victim of a prolonged storm of adversity.

[The following note has been kindly sent by Mr. Sydney Stephenson. It is in answer to an editorial request for an opinion on Sir A. Conan Doyle's theory that Edalji's astigmatism was of such an extreme kind as to have precluded the possibility of his committing the Wyrley cattle maiming outrages in the darkness of night-time. We have, further, the express assurance of Sir A. Conan Doyle that Mr. Edalji did not wear glasses, but that information did not reach us in time to communicate with Mr. Stephenson before going to press.—Ed. "M. P. and C."

To the Editor of The Medical Press and Circular.

Dear Sir,—Sir Arthur Conan Doyle's question, conveyed in his letter of January 13th last, raises wide issues. He inquires whether it is possible for anybody with, roughly, about nine diopters of myopia, together with 1.75 diopters of astigmatism in the right eye, to do what the police allege the convict George Edalji accomplished—namely, to have set forth on a pitch dark night, to have crossed the country for half a mile, climbing fences, finding gaps in hedges, and passing over a railway line, to have found and mutilated a pony which was loose in a large field, to have returned half a mile, and to have accomplished it all under thirty-five minutes, the limit of the possible time at his disposal. Assuming that Edalji was familiar with the countryside, and active in his movements, it seems to me that the short-sight from which he suffered would handicap him but little in his errand. Indeed, if the error of refraction were compensated by means of proper glasses, Edalji would probably be much in the position of a man with natural sight. It is known that some short-sighted persons are liable to a degree of so-called night blindness, and it is possible that Edalji suffered in this way. I do not gather from Sir Conan Doyle's letter whether this was or was not the case.

Yours faithfully,
Sydney Stephenson
(Editor, *Ophthalmoscope*).

January 14th, 1907.

To the Editor of The Medical Press and Circular.

Dear Sir,—Might I ask you in the cause of justice to permit me to put the following question to those of your readers who are engaged in eye practice:—

"Do you consider it physically possible for Mr. George Edalji, whose degree of myopic astigmatism as determined by retinoscopy under homatropine is—

Left eye ... ... – 8.25 Diop. spher.
– 1.75 Diop. cylindaxis 90°
Right eye ... ... – 8.75 Diop. spher.

to have set forth upon a pitch dark night with neither moon nor stars, to have crossed country for half a mile, climbing fences, finding gaps in hedges, and passing over a broad railway line, to have found and mutilated a pony which was loose in a large field, to have returned half a mile, and to have accomplished it all under thirty-five minutes—the limit of the possible time at his disposal?"

A consensus of scientific opinion upon this point would greatly aid me in getting justice for this young professional man condemned for an offence which, in my opinion, he could not possibly have committed.

I am, Sir, yours faithfully,
Arthur Conan Doyle.

Undershaw, Hindhead, Surrey,
January 13th, 1907.

CURRENT TOPICS.

Liverpool School Children.

The Education Bill of last session, thanks to the liberal degree of *odium theologicum* evinced by partisans, was successfully killed, and it can hardly be expected that the Government will attempt another settlement of the religious difficulty, at present at all events. Is it too much to plead that the non-contentious clauses of the bill, especially the one dealing with medical inspection, may be embodied in a short measure for passage through Parliament next session? The utmost unanimity in every part of the House of Commons prevails on the question of the necessity of medical supervision, and if any fillip were needed none more emphatic could be given than the revelations made by Dr. Arkle of Liverpool, in a paper read before the recent North of England Education Conference at Bradford. This gentleman was appointed by Liverpool City Council to make a thorough examination of the children of three typical Council schools and to compare his results with those obtained from the examination of well-to-do children. Dr. Arkle has taken twelve months to complete his investigations, and has produced a report which would be sensational if it were not scientifically and scrupulously exact. He examined all children in three Council schools, one in a good class district, one in a quarter where labour was fairly steady and regularly paid, and one in the poorest part of the city, and with them he compared the result of similar examinations conducted in secondary schools, where the children of the leading citizens of Liverpool are educated. After detailing his methods of research, weighing, measuring, examining sense organs, and so on, Dr. Arkle says: " One cannot fail to be startled—I had almost said appalled —at the unanimity of results, and the clearness with which they indicate a very terrible state of affairs. It is not only that they show deterioration as between the different schools, which one might naturally expect, but it is the mathematical precision with which the result is shown, and the extent to which the deterioration has gone, which makes the tables such gruesome reading." And such indeed they are. Without exception, the tables show that there is progressive want of development according to whether the parents are wealthy, well-paid, badly off, or very poor, the standard of physique in the children of the latter class being deplorable. Not only were the height and weight of the poorer children far below those of the better-off ones, but in eyesight and brainpower they were lamentably deficient, no less than 30 per cent. of the boys and 46 per cent. of the girls having defective vision. Inadequate feeding is shown to be the main cause, but insufficient clothing, want of tending, and deficiency of house room all contribute to produce a scathing indictment on latter-day civilisation.

Anti-Suicide Bureau.

THE saddest feature of rich and prosperous countries is that, side-by-side with luxury and happiness, there are many whose lives are so miserable that sooner or later they destroy themselves. The more complex the civilisation and the higher the level of education in a general way, the larger the proportion of suicides. In most European countries and in America during the last century the rate of suicide has risen alarmingly, and it is one of the problems to which preventive medicine must sooner or later turn its attention. It is no answer to the question of possibility of effective repression to say that most suicides are committed during attacks of insanity. That doubtless is true, but it merely means that such attacks should be prevented. It is well within the knowledge of all experienced practitioners that, especially in the case of young people, suicidal impulses which have appeared at certain junctures have been repressed by judicious treatment, and there are not a few people now living who after being frustrated in attempts to take their own lives have lived long and worked usefully. It is not possible for most educated and scientific people to support the Salvation Army in all its methods, but it is possible to regard that organisation as expressing a want in the community for some method of dealing with social wrongs and misfortunes, and " General " Booth's latest scheme, the opening of an Anti-Suicide Bureau, cannot fail to interest medical men, if only as a daring experiment. We may be prepared for startling figures, and indeed they have come already, for the officers announce that they have saved a hundred and four lives as the result of one week's work, but even discounting such announcements liberally, it is quite reasonable to suppose that some agency to which people under the influence of impulse can apply for help and protection, may be able to tide them over their period of mental aberration or place them under such restraint as will prevent them destroying themselves. It is, however, greatly to be hoped that the Salvation Army will take wise medical guidance in the formation and fashioning of their scheme, as their enthusiasm is notoriously apt to outrun their discretion.

The Union of London Medical Societies.

WE are glad to learn that the steps to promote a union of the various London societies are leading to a successful end. Only one society of primary importance—the Medical Society—has decided to remain out. Twelve have agreed to join the Union :—the British Electro-Therapeutic, British Gynæcological, British Laryngological, Rhinological and Otological, Clinical, Dermatological of Great Britain and Ireland, Dermatological of London, Epidemiological, Neurological, Odontological of Great Britain, Obstetrical, Pathological of London, Royal Medico-Chirurgical. Their energies should cover a fairly wide field, and in union the societies should constitute a representative academy of London medical science. There is always, however, a certain danger in overgrown societies of any sort, unless the sense of individual responsibility can be maintained. The members of a small group have a sense of responsibility and an *esprit de corps* unknown to the units of a crowd. It will be well, therefore, if the members of the various societies which soon will form a union see to it that they exert themselves as keenly under the new circumstances as they did under the old.

The Trypsin Treatment of Cancer.

IN the issue of *Nature* for January 10th, 1907, appears a letter from Dr. J. Beard. The writer quotes from the MEDICAL PRESS AND CIRCULAR of December 19th last, the following passage :—"Every medical man must deplore the frequent attempts which are made in the lay press to induce the public to believe that a cure for cancer has been discovered." Mr. Beard then proceeds :—"This is clear enough. Against it, I, a scientific man, now affirm not only that a cure has been found, but that my own work and discoveries have revealed *the cure*" (the italics are not our own). This clears the grounds so far as Dr. Beard's claims are concerned. As he is not a medical man, we own to having felt some curiosity as to the evidence on which a "scientific man" has seen fit to announce with such profound conviction a momentous medical discovery to the world. It appears that his evidence comes from New York in the shape of an article on trypsin treatment by Prof. W. J. Morton. That gentleman obtained apparent cure in two cases out of thirty, but as in one case the relief has so far lasted only one month, and in the other only four months, he who would conclude he had found a specific on such evidence must indeed be ignorant of the course of malignant disease in the human body. Dr. Beard, indeed, shows by his methods that he lacks the elementary principles of correct scientific observation. His claims to priority in the trypsin treatment fail to bear any close examination. After due enquiry, we ourselves are convinced that any credit that may be claimed in the matter belongs to Dr. Shaw-Mackenzie, who was the first to use trypsin upon a patient. In point of fact, Dr. Beard appears to have adopted the very preparation of the drug originally made up from Dr. Shaw-Mackenzie's formula. So far trypsin has failed to fulfil the claims that have been advanced in its favour, and its usefulness has not been confirmed by the Cancer Research Fund.

The King Edward's Hospital Fund Bill.

THE text of the King Edward's Hospital Fund Bill, published during the past week, will surprise even the most stolid. The Bill proposes in all seriousness to commit the entire administration of the Fund, lock, stock and barrel, into the hands of one person—the president of the Fund for the time being. He is to have power over capital and interest, to give or to withhold as he "in his uncontrolled discretion may from time to time think fit." In fact, the only limit imposed on his absolute power is the direction of the funds to hospitals in London ; inside this limit he can dispose of the funds without check, even handing them all to one hospital if he wish. The function of the General Council is to be purely advisory, and the members of it, as of all committees, and also the officers of the Fund, are to hold office at the pleasure of the president, who is himself to be the nominee of the Sovereign. In announcing his consent to the Bill now put forward, the present distinguished president, H.R.H. the Prince of Wales, stated that he acted on the advice of those most closely connected with the matter. We can only regret that they should have been so injudicious.

PERSONAL.

ON the 10th inst. H.R.H. the Duchess of Albany opened a new Infirmary for Children in Liverpool.

PROFESSOR RONALD ROSS, Sir Rupert Boyce, and Dr. John L. Todd, have received His Majesty's authority to accept and wear the Cross of the Commander of the Order of Leopold II., lately conferred on them by the King of the Belgians.

BY the will of M. Andrac, a wealthy landed proprietor, the Pasteur Institute is about to benefit to the extent of some £30,000 or £40,000.

DR. J. B. MCKENZIE ANDERSON has been appointed Visiting Physician to the Glasgow Royal Infirmary. Dr. Patrick King has been appointed anæsthetist to the same institution.

DR. SAMUEL EDGERLEY has been appointed Medical Superintendent of Menston Asylum, in place of the late Dr. J. G. McDowall, at a salary of £500 per annum, with furnished house, board and attendance. Dr. Edgerley has served on the medical staff continuously since 1897.

SURGEON-LIEUT.-COLONEL DAVID LENNOX, M.D., Surgeon-Major David Greig, M.A., M.B., F.R.C.S. Edin., and Surgeon-Captain George Halley, M.A., M.B., F.R.C.S.Edin., have been enrolled as Honorary Associates of the Grand Priory of the Hospital of St. John of Jerusalem.

MR. JOHN H. DEANE, L.R.C.S., L.R.C.P.Ed., was recently presented with a silver service by his friends on leaving Weston-super-Mare.

DR. COLIN HEYNSBERG, assistant Colonial Surgeon, Puttalam, Ceylon, is to succeed Dr. W. H. Meier, who is retiring, as Superintendent of the Leper Asylum, Hendala, Ceylon. The latter has occupied the office for the past twenty-seven years.

AT a meeting of the Board of Management of the Cardiff Infirmary on December 21st, the post of resident medical officer was obtained by Dr. W. R. Spencer Watkins. Dr. Sydney T. Champtaloup and Dr. Murdo M'Kinnon were appointed house surgeons.

A BUST of Dr. James Gregory, at one time Regius Professor of Physic at Edinburgh, has been presented to the University by Lord Leith of Fyvie.

DR. H. J. PALMER, of the Gamlingay District of the Caxton and Arrington Union, has been awarded the Government grant for successful vaccinations.

COLONEL LAMBKIN has been appointed lecturer on Syphilology at the Royal Army Medical College.

DR. A. H. FREELAND BARBOUR has been elected to the newly-instituted Lecturership in Systematic Clinical Gynæcology at Edinburgh University.

MR. H. T. BUTLIN will give the Hunterian Oration at the Royal College of Surgeons of England, at 4 o'clock, on February 14th.

MR. HENSLOWE WELLINGTON, M.R.C.S., L.R.C.P., Lecturer on Forensic Medicine at Westminster Hospital, Barrister-at-Law, has been elected a Corresponding Member of the French Medico-Legal Society.

DR. ALONZO GARCELON, a former Governor of the State of Maine and a past-President of the American Medical Association, has died at the patriarchal age of 93.

DR. A. S. GUBB, of Mustapha Supérieur, has been appointed Honorary Physician to the British Consulate at Algiers.

A Clinical Lecture
ON
OPTIC NEURITIS AND ITS RELATIONSHIP TO INTRACRANIAL TUMOURS.

By Dr. ROBERT A. FLEMING, F.R.C.P.E.,

Lecturer on the Principles and Practice of Medicine in the Edinburgh Medical School; Assistant Physician to the Edinburgh Royal Infirmary.

You have seen in these wards (*a*) not a few cases of intracranial tumour, and your attention has been directed to the significance both of the general clinical features common to most, if not all, cases, and also of those which localise more or less accurately the probable position of the tumour.

I wish to-day to discuss one of the chief general clinical features, namely, optic neuritis. While it is true that optic neuritis is found in a large proportion of cases of intracranial tumour, yet we must admit that our present knowledge of the precise nature of the neuritis and of the *modus operandi* of the tumour in producing it, is most unsatisfactory.

I purpose (1) discussing with you the ophthalmoscopic and microscopic appearances of optic neuritis as found in cases of intracranial tumour, and referring to the pathological appearances noted in a number of cases examined by myself. Under this head I shall also mention briefly the pathology of optic neuritis and the chief theories put forward. (2) We shall consider the nature of the tumours with which optic neuritis is most commonly associated, and—what is of much greater moment—the bearing of the site of the tumour on the incidence of optic neuritis. (3) Lastly, I shall refer, very briefly to treatment.

1. The optic neuritis met with in a case of intracranial tumour is generally double, although it may be more advanced in one eye, and sometimes this indicates the side on which the neoplasm is situated. The old name given to that optic neuritis which we are at present discussing, was "choked disc," or stauungspapille, because there is generally great pressure in the inter-sheath space or, at least, at the back of the eyeball, causing difficulty in the way of the blood returning by the retinal veins. This interference with the retinal vessels adds to, if it does not entirely cause, the choking of the disc or papilla.

The ophthalmoscopic appearances are easily recognised. The retinal arteries are small, the veins engorged, swollen and tortuous, and many small venous branches which are not noticeable normally are large enough to give the impression that these veins are unusually numerous, while the arteries have decreased in number as well as in size. The disc as a whole is red, the edges blurred, and to such an extent may the vessels project on the surface of the swollen papilla that they may require a +7D lens to focus them when the direct method of examination is used. At the edge of the disc the vessels bend backwards towards the retina; in front they are covered by exudation. There are usually numerous flame-shaped hæmorrhages in or near the disc, and the retina at the periphery of the disc shows evidence of exudation.

In cases where there is less pressure, the nerve head does not become so markedly "choked," but it has been conclusively proved that pressure in the inter-sheath space or at the back of the eyeball is not essential for the production of optic neuritis. In fact, an intense optic neuritis may be present without any pressure in either lymph spaces or vessels. It remains true, however, that "choked disc," is most marked where there is increased pressure in the inter-sheath space.

The optic neuritis may disappear, the inflammatory exudation and hæmorrhages being gradually absorbed, or else it may go on to a consecutive atrophy in which connective tissue replaces inflammatory exudation, the result being inevitable and permanent blindness. An attempt has been made to divide optic neuritis into stages, of which the first consists in congestion of the disc with some swelling, but such divisions are unnecessary and quite useless from a clinical standpoint. It is sufficient to know that early optic neuritis may never go on any further and that simple swelling of the papilla may be due to pressure behind the lamina cribrosa without sight being affected at all. Actual inflammation—in other words, true neuritis—must interfere sooner or later with vision.

Sight may fail early, even within twenty-four hours, or a wonderful preservation of visual acuity may persist with a high degree of "choked disc." The atrophic stage invariably leads sooner or later to blindness. In most cases of optic neuritis the common visual changes are an impairment of visual acuity and interference with the vision fields for colour, and especially a narrowing of the fields for green and red. The scotoma due normally to the optic disc is also often much enlarged.

Microscopically, I have never failed, in a case showing marked optic neuritis during life, to find definite changes in the optic nerves. Comparing a normal optic nerve (Fig. 1) with any of the other three figures, all of which are taken from photographs of optic nerves from cases of intracranial tumour in which well-defined optic neuritis was present, a marked nuclear increase is noted, and the nature of the increase is important. It is the neuroglial cells which chiefly undergo this increase in number, and the hyper-nucleation is largely due to proliferation of their nuclei. Ford Robertson has demonstrated the dual nature of so-called neuroglia, and that, cells he calls mesoglial, and which h

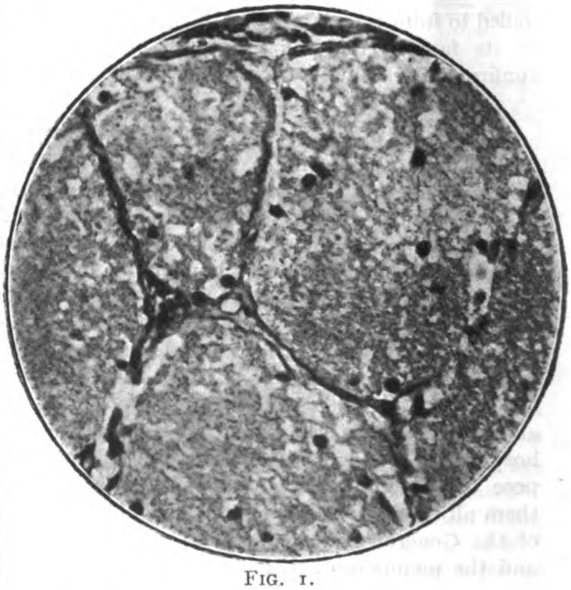

FIG. 1.

(*a*) Delivered to the lady medical students attending Dr. Bruce's wards in the Edinburgh Royal Infirmary.

has differentiated by the platinum method of staining, are distinct from the other cells to which the old name, neuroglia should be applied. These mesoglial cells do proliferate in optic neuritis, but not markedly, and they do not undergo the distinctive changes which are noted in the neuroglial cells. The normal neuroglial cells are branched cells, which vary greatly in size and in number and arrangement of their processes. The nuclei are oval or rounded, and the protoplasm, originally large in amount, is differentiated into fine, branching fibres. In optic neuritis these neuroglial cells, as distinct from the mesoglial, undergo the following changes, most of which are well seen in Figs. 2, 3, and 4. :—

(1.) They proliferate, and the proliferation studied in longitudinal sections shows that these cells are arranged in rows which aid the trabeculæ in supporting the optic nerve fibres.

(2.) The protoplasm of the cell is enormously increased and the processes become much more visible, extending quite obviously for long distances among the nerve fibres.

(3.) Many of the larger cells have a distinctly granular cytoplasm, and the periphery is often blurred; while in a few cells vacuolation of the protoplasm may be seen.

(4.) The nuclei of the cells become much larger, show definite karyokinetic figures, and, as a whole, stain more faintly than the normal neuroglial cells do. The nuclei are usually eccentrically placed, but this is a feature of many, if not most, normal neuroglial cells, and is merely enhanced by the great enlargement of the cells.

These neuroglial changes are best marked near the outer portion of the optic nerve, although in an advanced case they may be seen in any part of the transverse section, and appear to extend all along the optic nerve.

In a considerable series of cases of intracranial tumour in which I have examined the optic nerves after death, these changes were uniformly present, less marked, it is true, where sight was but little affected and the optic neuritis less advanced, and more definite where neuritis was giving place to atrophy. A few leucocytes were found, especially where meningitis was present; but the chief hypernucleation was accounted for by the proliferated neuroglial nuclei.

Some of the chief theories of optic neuritis demand a brief description, and I quote from a paper I wrote for the *Review of Neurology and Psychiatry* in 1904.

"The first theory, Von Graefe's, was that venous obstruction from increased intracranial pressure, especially affecting the cavernous sinus, might account for the optic neuritis. Needless to remark, the free anastomosis with facial and orbital veins renders this theory untenable. Broadbent, Manx, and others believed that the great pressure of lymph in the inter-sheath space might cause the optic neuritis. While it is true that a post-bulbar distension of the inter-sheath space is not uncommon, it may be slight even in extreme cases of optic neuritis. Schmidt included the lymph spaces, which form such an important means of communication between the inter-sheath space and the lymphatic channels in the nerve and pial sheath.

"It is usually pointed out in referring to these three theories, that while a very small tumour may produce the most intense optic neuritis, a very large one may cause none at all.

"Leber believes that there is an irritant of some kind in the cerebro-spinal fluid.

"Galezowski, Brailey, Edmonds, Juler, and others, hold that the irritant is not in the cerebro-spinal fluid, but in the brain tissue itself, by which it is directly conducted downwards to the optic nerve.

"Schweller and Hughlings Jackson suggest that the papillar inflammation is due to a reflex stimulation of the vaso-motor nerves of the disc.

"Deutschmann closely associates meningitis with optic neuritis, partly as the result of experiments on rabbits, in which he found that injecting staphylococci or tubercle bacilli into the subarachnoid space produced a more or less definite optic neuritis, and partly because in most cases of optic neuritis due to intracranial tumour, he describes a perineuritis with not infrequently a certain amount of localised meningitis in the neighbourhood of the tumour. Gowers believes that it is a descending neuritis which is present in intracranial tumour cases, and often associated with meningitis; the nuclear increase in the optic nerve and inter-sheath space he believes to be mostly of inflammatory origin."

It is difficult to say where the inflammation, unquestionably present, begins—whether at the papilla and ascending from there, or descending from the brain to the papilla. There is no evidence that optic neuritis is an ascending neuritis, and everything points to the correctness of a toxic theory, and, arguing by the hypertrophy of neuroglial cells which occurs in general paralysis of the insane, and other diseases which are certainly toxic, the changes just described favour a toxic hypothesis.

I cannot enter at greater length into this neuroglial hypertrophy, which certainly in not a few of my specimens suggests rather a condensation of neuroglial processes than a true hypertrophy; but I may be permitted to add that this hypertrophy differs from the neuroglial changes found in an optic atrophy not due to intracranial tumour, and that in albuminuric papillitis a somewhat similar, although less advanced, neuroglial change is present in numerous specimens I have examined.

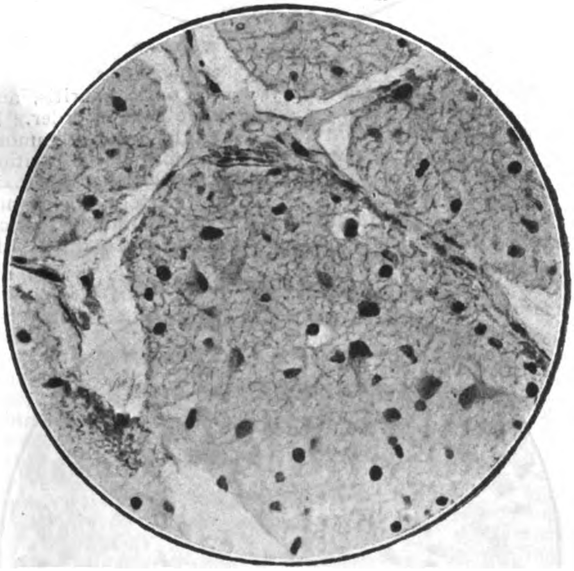

FIG. 2.

Fig. 2 is the photograph of a transverse section of an optic nerve from a case of gumma occurring in a female æt. 44. The gumma involved the left occipital lobe, extending into the brain from the membranes.

Fig. 3 is also a transverse section from a case of cerebellar tumour—or glioma—occurring in a man, æt. 40. There is marked optic atrophy present.

Fig. 4 is from a case of cerebellar tumour—a glioma—occurring in a girl, æt. 22.

The ghost-like appearance of some of the proliferated neuroglial nuclei is very well seen in these photographs.

There are therefore three kinds of so-called optic neuritis associated with intracranial tumour. There is (1) "choked disc," due to great intracranial pressure and in which sight may be long retained. There is (2) true inflammatory optic neuritis without much swelling of the papilla, and there is (3) an extreme degree of papillitis not due to mere choking of the disc. The second and third varieties are, I believe, of toxic origin, and in these sight usually suffers early and often severely. Figs. 2, 3, and 4 are taken from cases of (2) and (3), and are not merely instances of choked disc.

2. The nature and site of tumours causing optic neuritis. There is no question that a glioma, of all tumours, most constantly causes optic neuritis, and probably cysts and gummata come next in order. If we could assert that some particular type of tumour *always* produced optic neuritis, no matter the position in the brain in which it might chance to be, the toxic theory would be proved. Unfortunately, we cannot make this assertion and a tubercular tumour, which is perhaps least frequently associated with optic neuritis, will inevitably cause it should the tumour be situated in, for example, the cerebellum. Fully four-fifths of all cases of intracranial tumour are accompanied by optic neuritis, and this including tumours in regions with which optic neuritis is rarely associated. The cerebellum, I believe, is almost never the site of tumour without a coincident optic neuritis. I have collected nearly twenty cases of cerebellar neoplasm of different kinds, and in all definite optic neuritis was present after death. I am therefore disposed to consider the figure of 90 per cent. often given as being too low; optic neuritis is common in tumours involving the corpora quadrigemina.

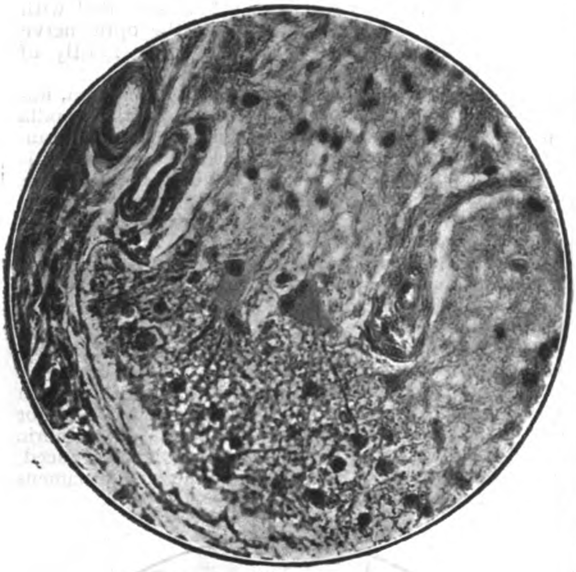

Fig. 3.

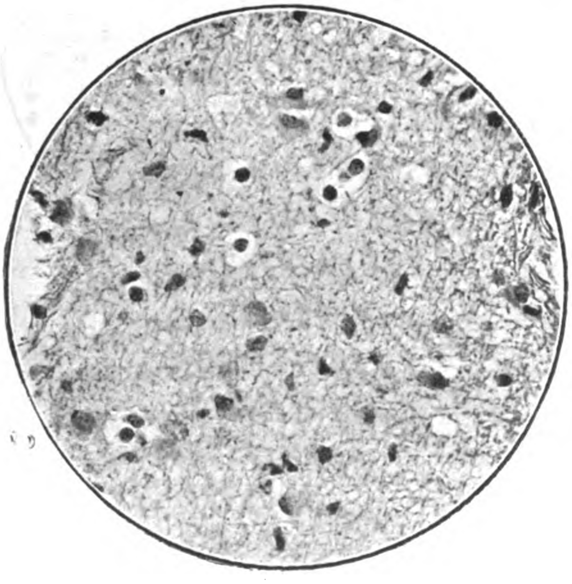

Fig. 4.

Tumours of the cerebral hemispheres generally cause optic neuritis, and especially if the frontal lobe is involved. According to Knies (who holds that choked disc is commonly the result of intracranial tumour, as distinct from a true optic neuritis resulting in atrophy) tumours in the anterior part of the frontal lobe may cause a true optic neuritis, which he thinks is due to a direct involvement of the nerve, and is therefore a descending neuritis. In this connection he points to the significance of the neuritis being unilateral and confined to the side of the tumour, a statement with which my experience of four cases does not agree. Meningeal tumours more rarely produce optic neuritis, and it is rare to find it in tumours of the medulla, pons, and corpus callosum.

3. What can be said with regard to treatment? I am and have been working for some years collecting and examining optic nerves from cases of intracranial tumours as well as optic nerves from other forms of intracranial disease, and I regret that my results are not yet available for this lecture. I have endeavoured to show that mere mechanical choking of the disc is not the only result of cerebral tumour, and that many cases have no such increased pressure in the lymph spaces or blood-vessels behind the eyeball, and yet the best treatment is unquestionably to attempt an operation which relieves any pressure which may be present.

Trephining the skull is, and should be, carried out in all cases of intracranial tumour where sight is threatened, whether we can localise the tumour or not, and it is a more satisfactory operation than trying to tap the inter-sheath space behind the eyeball. Lumbar puncture might in certain cases replace the more dangerous operation of trephining, where there is no interference with the lymph-channels in the brain. I cannot believe that relief of pressure is always necessary, and it is possible that the trephining operation and oozing of cerebro-spinal fluid may, as Horsley thinks, help in blighting the tumour. We know it does not always improve visual acuity, but it does so in more cases than can be explained by the choked disc theory. How it does so I cannot say. If the toxic theory of optic neuritis in cases of intracranial tumour is a correct one, we know as yet no remedy to apply which can do any good as an antagonising agent.

Note.—*A Clinical Lecture by a well-known teacher appears in each number of this journal. The lecture for next week's issue will be by Thos. Smith Clouston, M.D., F.R.C.P., Physician Superintendent, Royal Asylum, Edinburgh, Lecturer on Mental Diseases, University of Edinburgh, the subject being "The Mental Risks of Adolescence."*

ORIGINAL PAPERS.

SOME ASPECTS OF PRURITUS. (*a*)

By FRANK H. BARENDT, M.D.Lond., F.R.C.S.

Senior Physician, St. George's Hospital for Diseases of the Skin; Consulting Dermatologist, Royal Southern Hospital, Liverpool.

In choosing the subject, "Some Aspects of Pruritus," I am influenced by the importance of this at all times distressing condition. For, of the three chief plaintive symptoms—pain, disfigurement, and itching—that induce a patient to seek advice, pruritus is the one that is most frequently complained of in cutaneous diseases. Indeed, a patient states, often apologetically,

---

(*a*) Read before the Southport Medical Society, 1906.

that it is not so much that he is ill and in pain, as that he is compelled to seek relief from the intolerable itching, which, he assures us, is far worse than pain.

Disfigurement is largely a question of æstheticism and comeliness, depending as it does on the exposure to view of all those regions of the integument, viz., face, neck, and hands, that are usually uncovered by clothing. Thus, when these sites are free from eruption, and pain and itching elsewhere are absent, a patient is frequently unconscious of any skin-disease, and consequently his medical adviser remains also in ignorance, unless he examines the whole skin. This circumstance may account for the denial in good faith of any previous skin trouble by a patient who is suffering from some affection pointing indubitably to antecedent syphilis; and further, it explains how a medical man may misinterpret the nature of a local lesion in venereal diseases, unless he regularly and systematically insists upon inspection of the entire integument.

Syphilographers have rightly drawn attention to the absence of itching in cutaneous syphilides. This negative aspect of pruritus should ever be borne in mind, as slight maculo-papular syphilides do not generally obtrude themselves visually unless carefully sought for in daylight. Especially is this the case when they are sparsely scattered and confined to the dorsum and flanks.

Again, many psoriatics do not trouble themselves about their skin-disease so long as it does not attack the face or hands, or draw attention to the scalp. They feel well, have no pain, neither do they itch, thus confirming the dictum of Hebra that psoriasis is a disease of the healthy. In fact, if pruritus is at all present in such cases, I think we may with reason revise the diagnosis of psoriasis, or admit the presence of a concomitant disease.

Young ladies suffering from acne of the face and shoulders complain at times of itching; but no scratch effects are discernible, and I imagine that pruritus is put forward as a plaintive symptom to cloak the real reason, fearing lest the medical man belittling it should not give the affection that attention they so anxiously demand.

Leaving the negative aspect of pruritus, let me pass at once to the consideration of some of the positive aspects.

Itching, like most neuroses, is intimately associated with the borderland between health, *i.e.*, ease, and disease, and varies in intensity, not only with individuals, but also periodically in the individual and with the sex of the individual. That some people are more senstive, *i.e* itch more readily, than others, and *vice versa*, is a truism. Indeed, the mere mention of a flea, or the sight of any crawling creature, *e.g.*, an ant (*formica*), is sufficient to start an impulse to scratch —an example of pruritus (*formication*) where the cause is obviously psychical. On the other hand, how often do we see the skin of hospital patients bespotted with flea-bites, and not a sign of scratching, plainly showing how little sensitive their skin is, and therefore the absence of pruritus!

Between the normal cutaneous sensation, with its sense of well-being, and the most intolerable itching, stated to be the cause even of self-destruction, the difference is one of degree and not of kind. It is well known that, owing to the impinging hair of woollen underclothing, there are many who cannot wear it; and contrariwise, there are those whose personal comfort is best obtained by wearing the coarsest woollen underwear, and who cannot rest at night except between blankets. Neither of these conditions transgresses the limits of normal health: they afford an example of the personal equation which we must not forget in treatment. We speak of thin-skinned and thick-skinned persons frequently metaphorically, but the literal truth holds good, and the sensitive, highly-strung individual has a corresponding cutis, and similarly the lethargic and atrabilarian type. Temperament—in other words, the character of the nervous system—largely conditions the degree of pruritus, and explains how the graphic results on the skin differ so much in extent and in severity in different patients.

The causes of pruritus fall manifestly in two groups: (I.) those without, and (II.) those within the skin. Both, however, may graduate insensibly into one another. It is mainly those without, *i.e.*, the extra-dermal group, especially their effects, that I desire to dwell upon, although the time at my disposal is insufficient to take a complete purview of their complexity, ever made more intricate by the structural changes that accompany them. Itching causes scratching, the results of which vary as much in type as the efflorescences of skin-diseases do. Scratch lesions caused by finger-nails are not the sole distinctive objective signs of pruritus. Macules, papules, wheals, vesicles, open sores, and pigmented areæ—as final stages—are called into being by scratching, and the predominance of one or more of these eruptions affords frequently an indication of the severity and duration of the pruritus.

The extra-dermal group comprises mechanical irritation, *e.g.* pressure of clothes; chemical irritants, *e.g.* sweat, soap, and water, etc.; and the various animal and vegetable parasites.

The intra-dermal group includes variations in blood-pressure, hyperæmia and stasis, vascular alterations, *e.g.* varix in all degrees, and toxic states of the blood, *e.g.* icterus and diabetes mellitus, arsenic, etc.

In many diseases, pruritus as *cause* and scratched skin as *effect* become so intimately associated that a vicious circle is established, and clinically it may be impossible from the skin affection to diagnose whether the pruritus preceded or followed its evolution. I may illustrate this by referring to eczema of the lower third of the leg in a patient who has varicose veins. Does the stagnant blood pressing on the terminal fibrils produce the pruritus which causes the scratching, and this latter in turn the eczema? Or has some external irritant caused a small breach of the elevated epidermis, leading to exposure of nerve endings, which results in pruritus and subsequent scratching? Whatever the exciting cause may be, we know that scratching, beyond all doubt, increases and extends the area in which pruritus is felt. The relief that scratching often brings to a pruriginous area is a result of the numbing of the cutaneous nerves produced by capillary distension and exudation. When these subside, the nerves regain their function, and a repetition of the clinical phenomena takes place. As is well known, pruritus increases and decreases in intensity, and, if unrelieved by scratching, may disappear for varying periods. On the other hand, local pruritus may diffuse itself, so to speak, over areæ *far* from the original site. Consciousness is not necessary to pruritus, and patients may continue to scratch whilst asleep; it is only in intense pruritus, *e.g.* that accompanying scabies, that the act of scratching, being irresistible, hinders repose. Pruritus being determined both in extent and in severity by the amount of scratching that is done, as well as by the environment of the patient, accessibility of the scratching hand, or heel and toes, to the pruriginous area explains how certain areæ are more scratched than others. Furthermore, the method of dress may account for this. I may cite as an illustration the presence of pediculi on the pubes. The itching produced by these pests is most pronounced in males, and the scratching is sometimes so severe that in killing the pediculi by mercurial ointment the scratched skin passes simultaneously into acute dermatitis. The scratching here is clearly dependent on the accessibility of the scratching hand to the seat of irritation. In the female, however, pruritus vulvæ due to pediculi does not often come under observation, although I have seen the mons veneris teeming with pediculi in a case where the itching complained of was due to pediculi in the axillæ, no itching of the vulva was admitted by the patient, and no scratched skin was to be detected on examination. In the cases that have come under my observation, the intense itching has nearly always been in the axillæ, and the scratched skin plainly proved the truth of the statement. Here the accessibility of the scratching hand was determined by the method of dress, and apparently the intensity of the pruritus depended on the severity of the scratching. In men, pediculi attacking the axillary regions are of much less frequent occurrence.

Owing to the difference of buttoning the dress, I have noticed that in man more *maculæ cæruleæ* are present on the left inguinal region than on the right, and in women the right axilla showed similar superabundance over the left. I may mention in passing that these blue spots, pea in size, are pathognomonic of the presence of the crab-louse. They are produced by the salivary secretion of the insect. In left-handed patients I have noticed that in pruriginous eruptions, where universal, the scratched regions that are most typical are on the opposite side to those seen in right-handed patients; and more than once, from the extent and severity of the eruption being more developed over the right half of the trunk, I have correctly inferred the left-handedness of the individual.

Pruritus and Age-Incidence.—I believe for practical purposes we can surmise within certain limits the nature of the pruritus from its relation to age-incidence.

In *children*, the most frequent cause is urticaria papulosa or lichen urticatus or prurigo mitis. I may point out that this skin affection not infrequently supervenes upon the exanthemata. I have seen it after measles, scarlet fever, and especially after varicella. Jonathan Hutchinson, whose clinical observations have earned such well-merited fame, was the first to draw attention to this relationship with chicken-pox. Unfortunately, he gave the disease another name, varicella-prurigo, quite unnecessary from a dermatological point of view.

By way of parenthesis, let me say, the fewer the names we have to connote diseases which have a common pathology, the better it is for progress in cutaneous medicine. Indeed, terminology—especially the doublebarrelled kind so frequently indulged in in times past, and not even desisted from nowadays—I venture to think, has rather retarded our progress and rendered the study of skin-diseases, to the practitioner as well as to the student, more difficult than any other department of medicine.

This pruriginous eruption, passing successively through the stages of hyperæmia (like a red-ink smudge), of exudation (a small wheal and papule), is always most troublesome at night. The intense pruritus is revealed objectively by the scratched papules, which may become through inoculation of micro-organisms pustular; and this final stage, if pronounced, may lead to errors in diagnosis. Ecthyma was the term used to designate such pustular eruptions. Its distribution is general, with the exception of the mid-third of the trunk. Here little, if any, evidence of scratched papules is forthcoming, and the reason for this is the presence of the clothes, which prevent access of the scratching hand to the region. The exudate forming the wheals undergoes gradual absorption and leaves no trace of eruption behind. Elsewhere, the sites of the former scratched efflorescences are marked by pigment stains which are intermingled with successive crops of new efflorescences. The amount of pigment is an indication of the duration of the disease. Apart from a previous exanthem, the ætiology of this skin trouble is still a *questio vexata*. Gastro-intestinal disturbance, a labile nervous system, overclothing, abuse of soap and water, the presence of fleas and bugs, have severally been regarded as exciting causes. There is no doubt that a vulnerability of the skin must be present as well as any exciting cause, be it within or without the skin, and in treatment neither view must be overlooked to bring a troublesome case to a speedy and successful issue.

In *adults*, intense pruritus should always make us suspect the presence of scabies. This disease, of which our knowledge is complete—in striking contrast to other skin affections, for we know its ætiology, its pathology, its treatment—is one which, experienced clinicians state, sooner or later we are apt to overlook or misinterpret. Such a contingency is more likely to occur with patients who are more regularly clean than those who only are so spasmodically. The *primary* eruption consists of the familiar burrows with vesicles; the *secondary* eruption is due to the results of the vehement scratching, and insemination of pus organisms into the skin lesions thus produced; hence the term scabies pustulosa applied to the severe and always chronic form of the affection. The universal scratching originating in the local sites of the primary eruption is a good illustration of the diffusion of the sensation of itching all over the integument. For not only at the site, but in ever widening circles, does the scratching hand roam, so that in typical scabies there is scarcely a region of the body which does not plainly show scratch-marks and other efflorescences. In obscure cases, especially where the webs of the fingers fail to yield evidence, the nipple area in the female, and the penis in the male, should never be overlooked. The soft, delicate skin of these regions is a particularly favourite site for the burrows of the itch-mite, and scratch lesions in the vicinity, even if elsewhere ill-defined, should at once lead to the diagnosis of, and tratment for, itch. It is the neglect to examine these regions in obscure cases that so frequently leads to wrong diagnosis, for as it sometimes happens scabies is seen in those in whom we *prima facie* would not expect to find it. Furthermore, I may remind you that syphilis and scabies are from time to time to be seen in the same patient. Kaposi would scarcely admit any other method of conveyance of scabies except by actual skin-contact in bed. Careful attention to the favourite sites of the burrows, along with the presence of other accompanying signs of syphilis, will clench the diagnosis of the disease. The skin of scabietics is drier than normal; the secretion of the oil glands is diminished, due to reflex inhibition of the nerves regulating perspiration, as a result of the pruritus. This condition of the skin (*scabrities*) accounts not only for the statement of patients, who often persist that their blood is out of order, because, although treated successfully, they still complain of discomfort, if not of itching; but it also accounts for physicians, long after the discovery of the sarcoptes. admitting the presence of an itch diathesis, which, so to speak, permitted the development of the acarus. It is therefore important to treat the skin as well as kill the itch-mite, and to bear in mind that, in encompassing the destruction of the cause of the pruritus, its results as shown by the secondary eruption require equally as much attention. The parasiticide applications may even aggravate the skin lesions and actually increase the pruritus, which may mislead the medical adviser into thinking that the cause has not been removed. It is this irritability of the integument that demands allaying and not continued anti-scabietic treatment. This circumstance explains how it is that patients complain of itching long after the acarus has been destroyed; it, however, soon vanishes with emollient medication.

In *middle-aged* individuals, pruritus—be it general or local—should always induce us to examine carefully the urine for sugar, especially where the skin is dry and harsh to the touch. In women, pruritus vulvæ has, as a rule, produced through scratching intense dermatitis, and it is frequently the skin lesion that necessitates their seeking our advice. The itching is so intense that the severest form of eczema I have seen affecting the genital and femoral regions in women, has always been due to diabetes. At times, the pruritus may be general, and the ensuing dermatitis has been regarded as eczema; it is only after examination of the urine that the true cause has been discovered. I am of the opinion that pruritus is one of the earliest indications of diabetes mellitus, and for that very reason we should regularly examine the urine for sugar. For the onset of diabetes is always insidious at this age-period; indeed, it is notorious how difficult—nay, impossible—it is for us to say how long the patient has been a diabetic when he first seeks our advice for symptoms already plain to the practitioner, although he may have previously sought our advice for evanescent pruritus which we referred to some other cause, and relieved by some emollient. Pruritus has been stated to be symptomatic of gout and the gouty diathesis, and examination of the urine has been said to confirm such a nexus. Now, without disputing such ideas—for in every case where normal metabolism is deranged the skin as well as other organs must suffer—nevertheless, I believe that such pruritus originates in external causes and not in vitiated blood-states. Indeed, the most careful examination of the urine in severe cases of skin-disease, *e.g.* universal eczema, dermatitis herpetiformis—where *prima facie* we might expect such changes—has revealed in my experience no such deviation from the normal. The amount of urinary solids has not been diminished, and neither sugar nor albumen has been discovered. I do not say there may not be subtle changes in the urinary secretion, *but*, in the light of our present knowledge, these have not been detected by the tests we have at our command.

In the *aged*, phthiriasis may often be a cause of the intense pruritus that so frequently disturbs rest, so necessary to this period of existence. It is this disturbance that lowers their health out of all proportion to the cause at work. It is well to remember that the body-louse is not always confined to the poor and indigent. It would appear that the dry, furfuraceous, greaseless skin is especially attractive to those pests which live *in* the creases of the body garments and *on* the skin. The distribution of the scratch-marks with the central puncture of the insect is pathognomonic; and the itching, most marked over and below the shoulder-blades, may generalise till it is nigh universal. The pigmented condition of the skin, coupled with the misery of the patient, and the fact that it is often seen in tramps and vagabonds, has led older writers to describe it as the disease of the arraigned (*morbus reorum*). In the late epidemic of arsenical beer poisoning, the skin of many of the habitual drinkers produced the impression that they were suffering from phthiriasis of long standing, and not displaying the effects of chronic arsenic poisoning. The number of cases of morbus reorum admitted to the unions in Lancashire was truly astonishing, until the discovery was made of arsenic in the beer they had taken!

Although we know the cause of the pruritus in phthiriasis, it is curious how patients refer their itching to some blood-state. This very fact, to my mind, shows that the state of the skin is abnormal, being chiefly deficient in grease. The inunction of lanolin alone, and stoving the under-garments, has effected a cure; although, as is well-known, the best remedy is *unguentum Hydrargyri Ammoniati.* As the aged feel the want of heat more than the young and robust, the body vest is frequently not removed at bedtime. It is important to insist upon a change in this respect; for it is surprising how such a point may be overlooked by the medical adviser, and naturally ignored by the patient, who resumes his body vest after treatment, while carefully stoving his flannel shirt.

With regard to treatment, "Remove the cause, and the effect will cease," is a trite saying, and yet in the practice of medicine we soon realise that other matters are of equal importance. I allude to the immediate environment of the skin, the changing conditions to which it is daily exposed, and the ever-varying changes of temperature to which it is subjected. There is no doubt that the character of the underclothing and the continued use of soap and water are *essential* points to be considered in the treatment of pruritus. I have already mentioned the itching that is produced by woollen garments, but mechanical pressure long continued during waking hours may induce pruritus when undressing, which may persist for some time, and so interfere with sleep. It is a familiar fact to most of us, that a sensation akin to itching is experienced when undressing, and we instinctively pass our hands over our body, if not to scratch, at any rate to gratify a sensation of relief from pressure. The pressure of the braces, garters, of the corset in women, of footgear, when removed, often induces one to scratch, due to the flux of blood and concomitant compression of the nerve endings in the skin. In some persons the cold air produces itching, accompanied by the state of the skin known as *cutis anserina.* In such, undressing should be done in a warm room, and the night-gear and bed previously warmed. The old-fashioned copper heating-pan was exceedingly useful for removing the cold sensation of the linen sheets our forefathers so much affected.

That soap and water are injurious in eczema and should be prohibited is well known. But what perhaps is not so well realised, is their *harmfulness* whenever the horny layer of the epidermis is broken, signalled for the first time to the patient's consciousness by itching. He not infrequently ascribes such itching to something on his skin, to his overlooking the region in his ablutions, and forthwith adds fuel to the fire by using more soap and water, and so washing more vigorously. They are good servants but bad masters; and if cleanliness is next to godliness, assuredly over-cleanliness is next to pruritus. It is the daily use of too much soap, and as a result the excessive removal of the natural grease of the skin, that is responsible for the pruritus that patients experience after their morning bath. This excessive washing tends to bring their skin into a condition akin to *xerodermia,* a congenital disease characterised by a deficiency of the natural oil of the skin found in the sweat as well as in the sebaceous glands.

Many cases of that distressing condition, *pruritus ani,* if not caused by the abuse of the bidet, are distinctly aggravated by the over-use of soap and water. If the distended hæmorrhoidal vein has caused a breach in the horny layer of the epidermis, and through nerve exposure started pruritus, soap and water are the very best and surest—because so regularly used—promoters of the continuation of the pruritus. It is therefore of prime importance to decide at the outset in the treatment of pruritus whether soap and water should be used with caution, or absolutely prohibited. But this prohibition does not mean absence of cleanliness; it can be quite well obtained—and, I venture to say, without interfering one whit with treatment—by using olive oil in their place. As a type of soap I take the *sapo durus* B.P.: this is an oleate and palmitate (chiefly the former) of soda, made from olive oil and soda. When used for washing, every soap undergoes partial decomposition, setting free alkali; and this is the ingredient that is so harmful to the broken epidermis. Therefore, if we exclude the alkali altogether from the soap the olive oil remains, and being fluid, we can dispense with water. It is only when we have assured ourselves that the epidermis is intact and the pruritus absent that we should permit the resumption of soap and water. Even then, after a bath and drying, it is a good plan to recommend the application of olive oil to any pruriginous areas. It is in the treatment of pruritus due to diabetes, when the function of the sudoriparous and sebaceous glands is in abeyance, that the use of oil or oil and lanolin is of such signal benefit. In the aged, the shrinking of the panniculus adiposus and the sluggish secretion of perspiration predispose to pruritus senilis; in such patients the value of inunction of emollients (especially after a warm bath) in alleviating the itching is seen. The use of a dusting powder is so beneficial because its particles sink into the crevices of the fissured epidermis, and thus exclude all sources of irritation from the nerve endings.

In conclusion, I may state, my object has been, not to follow the text-book description of pruriginous diseases, but to accentuate the clinical symptom of pruritus, to unravel its graphic effects on the skin, and so working backwards, arrive at a diagnosis of the disease. Then, taking into consideration the manifold conditions that have permitted the evolution of the disease, if not indeed fretted it into persistence, I have endeavoured to work forward to a favourable prognosis, and with it the prevention of its return.

We may not always succeed in ascertaining the cause of the pruritus, but we *do* know how important it is to combat the conditions which favour its development and persistence.

I have cited examples of pruritus in disease most frequently seen in my experience in the four stages of life—childhood, adult life, middle age, and old age. I need not say that pruritus, from the patient's point of view, is in truth a *disease;* his comfort is gone and peace of mind often gravely ruffled. It therefore behoves us to remember *his* view, and in our efforts to restore him to health we should not be so ready to apply the most recent remedy hailing now from Germany, now from America—not that I say it may not be useful—but rather at all times be vigilant of the conditions under which the itching may be produced, and to remember that it is not in the multiplicity of medicaments—old-fangled or new-fangled—but in the method of treatment and attention to detail that success is to be sought.

If the remarks I have made have anything of value, it is because they have been the result of personal experience. I believe that in the practice of medicine, as in other arts, the personal element counts. But it is not in an egoistic spirit that I have ventured to address you to-night. It is simply because I thought that, having honoured me with an invitation, I could not show my appreciation of such honour better than by giving you my views on such an important symptom in cutaneous medicine.

THE MEDICAL INSPECTION OF SCHOOL CHILDREN. (a)

By A. SEPTIMUS ARKLE, M.B.Cantab., M.R.C.S.Eng.

(Liverpool).

This paper is based on the results of an inquiry into the physical and mental condition of children at certain ages in the various grade schools in Liverpool and its neighbourhood, and the subject is one of great importance at the present day, when the feeding of poor children in schools occupies such a prominent position in the minds of all who take an interest in the rising generation.

A total of 2,477 children were medically examined, of whom 366 were from secondary schools. The elementary schools were divided into three groups, A, B, C; A, representing children of well-to-do parents; B representing children of the lower shop-keeping and labouring class, the latter being supposed to be in constant employment; C representing children from a lower stratum, the parents of whom were either out of employment altogether or whose employment was only casual.

The secondary schools were selected in comparison as representing children who enjoy every advantage as regards food and clothing. Class C consists to a considerable extent of children who do not get enough food for their requirements, and who are also frequently insufficiently clad, and it furnishes a very striking contrast to the secondary school class.

The author states that the material as a whole is good, and he has seen none to equal it either in France, Germany, or Italy. "I am sure," he says, "I saw more deformed children in one day in Genoa than in a year's work in the schools of Liverpool, and I have seen more lateral curvature in the streets of Berlin than in all the schools I have examined put together." If, then, the material is as good as it appears to be, there must be serious mismanagement of it somewhere to produce the state of things he met with in actual investigation. He says: "One cannot fail to be startled—I had almost said appalled—at the unanimity (*sic*) of the results, and the clearness with which they indicate a very terrible state of affairs." The picture projected into the imagination by the tables here given is indeed a pitiful one. In the four classes of schools examined there is a distinct lowering of the physique of the children step by step, and this down-grade tendency corresponds to the limitation of the power of the parents to feed and clothe their children.

The lowering of physique in the different schools, from secondary schools to Class A, from Class A to Class B, and from Class B to Class C, cannot fail to attract attention. The comparison was made of children at corresponding ages, the first being made of children at 7 years of age, the next children of 11, and, lastly, children of 14. The tables give the height and weight at the ages named.

Measurement of children at 7 gives:—

	ft.	ins.
Secondary Schools	3	11.8
Council School "A"	3	9.3
,, "B"	3	8.35
,, "C"	3	8

The total difference between the secondary schools and "C" is 3.8 inches. At 11 years of age we find:—

	ft.	ins.
Secondary Schools	4	7.5
Council School "A"	4	5.1
,, "B"	4	3.8
,, "C"	4	1.7

showing a total difference of 5.75 inches. At 14 years of age we get:—

	ft.	ins.
Secondary Schools	5	1.75
Council School "A"	4	10.2
,, "B"	4	8.25
,, "C"	4	7.25

showing that the total difference has increased to 6.5 inches, or more than half a foot.

Taking the weights of the boys, we find the difference even more marked. At 7 years old the boys weigh:—

	st.	lbs.
Secondary Schools	3	7.3
Council School "A"	3	2.1
,, "B"	3	1
,, "C"	3	1

showing a total difference from the secondary schools to "C" of 6.3 pounds. At 11 years of age the weights are:—

	st.	lbs.
Secondary Schools	5	0.26
Council School "A"	4	5.45
,, "B"	4	3.05
,, "C"	3	13.5

showing a difference of 1st. 0.75lbs. Whilst at 14 years of age we get:—

	st.	lbs.
Secondary Schools	6	10.5
Council School "A"	5	5.82
,, "B"	5	5.87
,, "C"	5	1.14

showing that the total difference has reached the magnitude of 1st. 9.25lbs.

There is little need to enlarge on the tale that is here told with such eloquence, but another and much more powerful one might have been told, and we may hear it some day. There can be no doubt there is plenty of material for one, if anyone would only take the trouble to collect it. Supposing, instead of taking the whole of Class C for comparison with secondary schools, the children of the very poor only had been selected; the tables would have shown a wide difference. As they stand many children of Class C would be well fed and well looked after in every way.

Again, if all children taken to workhouses and children's shelters were weighed on admission, as they probably are, and the figures were made available for showing the ravages of starvation and insufficient food in the young, it might be possible to move Government so that in the course of time it might deem legislation on the subject as of almost equal importance to a Constitution for the Orange River Colony, Votes to Women, or the Repatriation of Chinamen.

Her Royal Highness Princess Christian, accompanied by Mrs. Dick-Cunyngham, on Saturday afternoon visited the Crèche at Windsor, and was received by the Rev. F. M. Hargreaves, Mrs. Hargreaves (hon. treasurer), Miss Martin (hon. secretary), Major Martin, Lady Edward Spencer-Churchill, Lady Clementine Walsh, and Mrs. Seymour Corkran. Her Royal Highness, who is the founder and patroness of the institution, received a number of "pound" gifts in aid of the crèche, and distributed to the poor parents of the infants daily catered for in the nursery parcels of warm clothing allotted from the Berks and Bucks Needlework Guild, of which Princess Henry of Battenberg is founder and patroness.

(a) Abstract of paper read at the North of England Educational Conference, held at Bradford, January 9th, 1907.

LETTER TO A YOUNG PRACTITIONER ABOUT TO COMMENCE PRACTICE. (a)

By Dr. G. CORNU

(La Clinique.)

My dear young fellow-practitioner.—Just a month ago you received magisterial sanction and acquired the right, conferred by the State, to intervene between life and death. One is a labyrinth, the other an abyss. You will have to fight your way between two mysteries, with your mind disturbed by the appeals or the remonstrances of human suffering. Your foremost duty is modesty. You have but to glance at the diploma which has just been handed to you. It is written on the skin of an ass, but do not resent the inference, for it is a tacit injunction to be patient, courageous and gentle. You think you are "out of the wood," but a new and tiresome apprenticeship awaits you. You are now entitled to call yourself doctor; it remains for you to become a practitioner.

So far you have practised art for art's sake. Now you will have to practise it for a livelihood, and all your ideas will be upset in the process. At the hospital the patients belonged to you; in future you will belong to the patient who employs and pays you. You will ever have to bear in mind the practical issues of life, your professional reputation and the obligation to please. Your prescriptions will no longer be inspired exclusively by the goddess science, speaking as from a throne. They will have to be modified to suit the whims, the tastes, the indifference or the passions of your "customer," and, as you lack the authority that belongs, perhaps, to superlative diplomas, they will have to fall in with the prejudices of your environment. Before you have thrice listened to the râles of pneumonia you will forswear your masters by ordering a blister in deference to your patient's expectations. You will prescribe useless drugs because you find it necessary to do something and have to justify your attendance. I said just now that your first duty was *modesty*, but your first obligation is cocksureness. *The duty* is your private affair, the obligation is for *show*. One is a scientific duty, the other a trade obligation. You have no right to hesitate in arriving at a diagnosis. Yes, you who, it may be, left the schools with the idea that medicine is a sacred calling, that it would be yours to cure or to console, you, who have so often placed your enquiring hands on that painful vacuum, man, that you have become a sort of sentimental materialist, take my word for it forthwith that in the struggle for existence upon which you are about to enter, sentimentalism is a weakness, and, by contrast, even a psychological danger.

I fancy I see you at the bedside of your first patient! His state is grave, but not past hope, and because everyone is in tears your pity is moved. Imprudent man! You seek to reassure them! Your far-seeing science enables you to relieve their anxiety. Recovery ensues, and the good woman who was the noisiest among the weepers is already muttering that, after all, the malady was not as serious as it seemed, and the convalescent, in view of your fees, will boast to you of his strong constitution, of nature's resources, and discounts his esteem and his bill in proportion to the consolations you have offered him.

Your next patient is incurable. You see that his case is hopeless, and you picture to yourself what would be your own despair were he your brother or your son. As the end is still distant, your delicacy leads you to hide the gravity of the case from his immediate relatives. Six months hence will be quite early enough, you say to yourself, and in the meantime how many anxious days and restless nights you will have spared them. What a mistake! In six months they will reproach you with having disguised the truth at a time when it was conceivably still possible to do something since the papers are full of advertisements of remedies that cure this particular disease. If they called in a doctor it was, of course, to know exactly how matters stood, but very likely you did not know yourself!

Your sentimentalism will hinder you, too, when you limit the number of your visits in order not to scare a nervous patient whose recovery is, moreover, quite certain. If, on the other hand, his exaggerated apprehensions or his vanity oblige you to be constantly in attendance, take heed lest a false conception of honesty make you hesitate to visit him unnecessarily.

Take care not to raise a regrettable misunderstanding between you and humanity at the outset. Never look for gratitude. This flower of evil may raise its head in the shadow of pain, but it fades in the first rays of convalescence, and it will be sent back to you sere and yellow between the leaves of your bill. For the matter of that, what claim have you to gratitude? Whatever service you may have rendered, after all, you were only following your calling, and as you follow it for money, as soon as you have been paid you are quits. If some eccentric person happens to think that something remains due to you after he has handed over the cash, look upon the fact as an anomaly, a purely subjective mistake as to the scope of a social obligation. Do not set it up either as an example or a precedent. Strictly speaking, it is you who ought to be grateful to the patient whose life you have saved, for he has afforded you an opportunity, among the many instances in which your intervention was futile or useless, to show that you and your art are necessary evils. Moreover, he will have flattered your intelligence and renewed your courage.

Lastly, get well into your head that your reputation depends as little as may be on your scientific attainments and your devotion to duty. Your science! Who is to estimate it? The outsiders upon whom you lavish it are more than ignorant of it. You see it through the deforming prism of a thousand false ideas and unsurmountable prejudices. Shall they base their estimate on the results? But to do that they would require to be able to form a sound opinion of the causes and distinguish the starting-points. The ignorant or unscrupulous practitioner who has cured a hysterical patient of epilepsy, will acquire vastly greater renown than the clear-sighted and conscientious physician whose exact diagnosis sets their fears at rest.

Devotion to duty? Do you know what the public understand by this term? Not your personal sacrifice at the bedside of the cholera patient, a merely trade risk, for the man who tiles the roof displays the same sort of heroism. Nor is it the part you directly take in the care of your patient, the first day or two they will thank you, but afterwards they will consider it to be incumbent upon you. No, it is simply the promptness with which you respond to their call. And your haste, especially in country practice, will soon become a snare. You will be expected to put in an appearance immediately for the most trifling thing, or simply because your visit at such an hour will cause less inconvenience than at such another. When the day comes that your gorge rises at seeing your goodness so meanly taken advantage of, vexed at having kept waiting a patient far more seriously ill but less insistent in order to minister to the caprice of one who has a cold in the head and treats you as his domestic; when, I repeat, you decide to put your foot down, you will call down upon yourself more anathemata than a well-established gruffness would ever have excited.

To sum up, practising for the public an art which it is incapable of judging, you must not hope to create an impression by your knowledge of disease, but by your knowledge of men. The more illusions you have brought into your career the more will the reality have bruised your delicacy of intelligence and sentiment, the deeper will be your fall and the more dangerous the depression which experience is holding in wait for you.

Humanity is a landscape that must be looked at as a whole and viewed from the summit of the mountain called disdain. Philanthropy, disdain, they may strike you as a strange contradiction in terms. For those who, like you, have to live face to face with the nakedest reality, one is to the other the only asylum and the indispensable refuge. On the road whither you are summoned by human suffering, through the pitfalls and thorny bushes of foolishness, if your respect for mankind is not protected by the triple armour of which the poet sings, the last vestige will have been carried away before you have been five years in practise. At that stage you will know, not the fugitive, indulgent disdain that smiles and pardons, but the contempt that holds fast, that mocks and extorts.

(a) [The above charming little monologue from the pen of Dr. G. Cornu (La Clinique), appears to us to merit the honour of translation. If we cannot flatter ourselves to have done justice to the literary elegance and sparkling irony of the original, we have at any rate extracted some sound observations and practical wisdom.—Ed. 'M. P. and C."]

I am telling you all this because I credit you with a generous mind. For if Nature has not implanted in your bosom too abstract a conception of science and a troublesome human ideal, all my warnings are idle. You will make your way surely and easily. Offer a cock on the shrine of Esculapius "in settlement of account," and pray the god who bears the twined serpents to maintain you throughout your career in a state of diligent mediocrity. On much the same intellectual level as the public whom you serve you will please without effort. Your object in life will not be to cure your patient, but to pile up visits. Your cures will be slow, and even your mistakes remunerative. More assiduous at the bedside than disease itself, the latter will have vanished without your having ceased to wrestle with it, and the convalescent, finding with satisfaction that you do not neglect him, will hardly venture to be restored to health. Conveniently propped up by books that you have ill-mastered, or bold "lines of practice," you will elaborate for yourself an imperturbable and simple rule of thumb. You will be the trustworthy practitioner who does not allow his rules of conduct to be swayed by that impertinent entity called experience, and without running the risk of losing your way in the chanceful search after causes, you will be the impulsive therapeutist who gives each symptom tit-for-tat, the simple strategist who always rushes to the cannon's mouth, in whose hands polypharmacy provides a liberal supply of shrapnel to make up for any lack of precision in aim. You will be the doctor who gives disquieting diagnoses and guarded prognoses, who daily cures manifold cases of diphtheria and meningitis. No patient will ever leave your consulting-room without being drugged to the full. You will be the blood-purifier, the disperser of tumours, the bone-setter, nay, in deference to the modern trend of ideas, you will squander serums galore. On the other hand, you will shake hands with Dick, Tom and Harry, and when you raise your hat the gesture will be the equivalent of a smile. Masked by the dust of your automobile with its indefatigable horn, the passers-by will celebrate your triumph in dithyrambic and sternutatory fashion, a triumph, moreover, which can be converted into cash. *Aurea mediocritas*, which may be freely translated "wealth to mediocrity." Far more, in the course of time you will acquire a peace of mind that would never have been yours had you taken pure science as your guide. You will be the fly fluttering round the coach sunk in the mud of human health, satisfied with its achievements and proud of its buzzing restlessness.

What! this career has no attractions for you?

Well, I should be sorry for any words of mine to cast discouragement on honest endeavour. I have no doubt inconsiderately laid on the colours too thickly. I only wished to warn you of the perils of the road. But there are concessions that are permissible and honourable, because necessary, between one's principles and the implacable reality. To realise how far you may compromise with your science and your self-respect without betraying one or the other, to know how to capture the esteem of an unenlightened public, is a problem which you may set yourself to solve in perfect honesty of purpose. I could only point to the difficulties, you alone can overcome them, and this is what I meant when I said, "You are now a doctor; it remains for you to become a practitioner."

THE OUT-PATIENTS' ROOM.

METROPOLITAN HOSPITAL.

Rheumatic Heart Disease and Blood Pressure.

By Leonard Williams, M.D., M.R.C.P.,
Assistant Physician to the Hospital; Physician to the French Hospital in London.

This woman, whose age is 36, has recently been discharged from the wards, where she was under my care. She was admitted with all the classical signs of uncompensated mitral regurgitation, namely, œdema of the extremities, pulsating liver, orthopnœa, enlarged right ventricle and apical systolic murmur. Her systolic blood pressure on admission was 160 mm. Hg., which is definitely above the normal. This is a very important fact, to which I shall return presently; but before discussing it I want to explain how this woman was treated. Her history showed that she had had chorea as a child, and rheumatic fever in early adult life, so that we were fortunately in no doubt as to whether or not her morbus cardis was of rheumatic origin. Doubts on this point are sometimes very difficult to clear, but it is very necessary that they should be cleared, because the line of treatment to be adopted in a case of rheumatic origin is very different from, one might almost say is diametrically opposed to, that which is proper to a case where the morbus cardis is secondary to arterial or renal disease. In the first case you may give digitalis boldly and with confidence, whereas in the second, if you give it at all, you do so at a risk to your patient's life which is by no means inconsiderable. This woman, then, was given digitalis; but not at first. There is no use in giving digitalis until the path has been prepared for it by brisk and even drastic purgation. If you do not purge your patient, the digitalis will not act; and you may always gauge the efficacy of the purgation by the promptitude with which the digitalis increases the urinary output, and slows and steadies the pulse. Properly employed, digitalis is a soverign remedy in these cases, and if it fails to act as such, then you may be quite sure that the fault lies not with the drug, but with the method of its employment. The drug may be at fault in the sense that the particular preparation used may not be an active one, for there is no drug whose preparations vary more in individual samples than digitalis. The ticture is notoriously unreliable in this respect. A freshly made cold infusion is infinitely more trustworthy.

To return to the question of blood pressure in these cases. On the face of it one would suppose that if ever such a condition as unduly low arterial tension could exist, it would be typically present in a case of uncompensated mitral disease. The systemic arteries are here but partially supplied with blood, the great mass of which is stagnating in the veins and pulmonary system. We found, nevertheless, in this case, and you will find the same in all similar cases, that so far from being reduced, the arterial tension as repeatedly measured by the manometer was not below normal, but definitely and unmistakably above normal. Now, what is the explanation of this fact? If you will ask yourselves a very simple question, the correct answer thereto will supply the solution to this apparent riddle. The question is, "What is the object with which the blood pressure is maintained at or above a certain level?" The answer is, "In order that the periphery, all parts of the periphery, but more especially one part, namely, the medulla, may be adequately supplied with oxygenated blood." Now, if the pressure in the venous system is unduly high, as in cases of uncompensated mitral stenosis it inevitably must be, it follows that if the medulla is to be properly supplied, the pressure in the arteries must rise above that of the veins. If it fails to do so the medulla is starved and the animal dies. In these cases, therefore, so far from finding a low arterial tension we find a high one, and the height of the tension in the arteries is in some degree a measure of the block in the pulmonary circulation: for the arterial tension must rise until it is strong enough to overcome the venous stasis. These considerations supply the solution to another clinical riddle, namely, the phenomenon of orthopnœa. It is a riddle to a good many, that people with a labouring heart should instinctively adopt a position, namely, the sitting position, which imposes an unnecessary amount of work upon the crippled central organ. But we have to remember that this central organ, the heart, is after all only the servant of the medulla, and that consequently if their interests should clash, it is the heart which must yield. Thus it happens that the paramount necessity for arterial blood on the part of the bulb causes the patient to adopt an attitude which, though it may tax the heart, aids the medulla by favouring the return of venous blood from the brain to the heart. He sits up, because by so doing he calls the force of gravity to his assistance in hurrying the venous blood away from the cranial cavity, to make room for the all-essential arterial tide. This patient has passed successfully through her trying ordeal, and she is now well; as well, that is, as she is ever likely to be. She may look forward to the future with a considerable degree of hope. That, unfortunately, is the best we can say; for of all the means of risking disappointment and loss of credit, positive prognosis in heart disease is at once the most dangerous and the least profitable.

OPERATING THEATRES.

NORTH-WEST LONDON HOSPITAL.

Suppuration of the Shoulder-joint Simulating Mammary Abscess.—Mr. Mayo Collier operated on a married woman, æt. 45, who had been admitted with the following history: ten days before she had applied at the out-patient department complaining of pain and tenderness at the lower and inner aspect of the left axilla; she stated that a week before this she had been extremely ill, and had suffered from rheumatism of the left shoulder. There was no history of injury or previous trouble in this region. The house surgeon who first saw the case diagnosed two collections of fluid, one on the lower and inner aspect of the left breast, the other near the anterior border of the latissimus dorsi, about four inches below the axilla. The temperature was normal when the patient was first seen, the lungs, too, were apparently normal; there was no point of suppuration in any part of the body excepting that the patient had several carious and painful stumps. The woman had not recently been parturient, and up to this period her general health had been good. There was no vaginal discharge, but this was not ascertained till her admission into the hospital. At first the patient was not admitted, but was treated as an out-patient. The two collections of fluid, which proved to be pus, were opened and drained antiseptically. Iron and strychnine were administered internally, and instructions were given to the woman to attend daily at the hospital for surgical treatment and supervision. The case not progressing satisfactorily, the discharge still continuing with an elevation of temperature, Mr. Collier, when he first saw the patient and after he had made a careful examination of the breast and of its surrounding parts, said that no cause was apparent for the two foci of suppuration; the breast on this side was soft and elastic and seemed to be quite normal; there was no disease of the ribs or periosteum, no local skin affection which could in any way account for the suppuration. The general condition of the patient, however, he pointed out, was not satisfactory: her face indicated that something was wrong, there was a hectic flush on each cheek, the temperature varied from 99 to 101 at night, and moist sounds could be heard over each base; the pulse was fast and the appetite was fanciful; there was no other focus of suppuration except that the teeth were carious and the surrounding gums inflamed. On movement of the corresponding shoulder no complaint was made, but an area of redness over the bicipital groove about four inches below the shoulder-joint gave a clue to the real condition of things. Mr. Collier incised this area of redness, and found that a probe could be passed in the track of the tendon of the biceps muscle into the shoulder joint. The shoulder was then further manipulated, and still grating could be felt, showing that the head of the humerus and the glenoid cavity were divested of cartilage. Mr. Collier pointed out that it was a common experience to find that in chronic and acute suppuration of the hip-joint abscesses would present themselves in the thigh in various positions, and that the first indication of disease would announce itself in these directions. An abscess in Scarpa's triangle or in front of the ilio-tibial band and posterior to the gluteal region was quite a common experience in connection with hip-joint disease, but an abscess to present itself in the neighbourhood of the shoulder-joint without first directing attention to disease of the articulation was one of the rarest conditions in surgical experience. The shoulder-joint was so placed, so superficial, and so affected by the smallest movements of the upper limb that any pathological condition of the articulation was usually early apparent to the patient or to the attendant. It was quite unusual for acute suppuration causing perforation of the capsule and discharge of its contents into the surrounding tissues to take place without the patient complaining of serious loss of function in this joint. As a matter of fact, the absence of pain and the loss of function in the joint had misguided the medical attendant in his first inspection of the condition. The case was treated in the first place as a mammary abscess; it was not until the patient had been admitted to the hospital that the absence of improvement and the general hectic condition had raised suspicions that something more was present than a mammary abscess. The small area of redness over the bicipital groove gave the clue to the real condition of things. Mr. Collier said that the rarity of this condition was sufficient excuse for the absence of a complete diagnosis before admission to the hospital, but investigation of the shoulder-joint proved beyond doubt that the case was from the first one of septic inflammation of the shoulder-joint, probably following as a direct result of the carious condition of the teeth in a patient whose health was decidedly below par. Mr. Collier passed a probe into the sinus on the bicipital groove, and incised the tissues up to and as far as the acromion process. The joint was entered and opened freely, and irrigated with a solution of 1 in 40 carbolic; a large drainage tube was then inserted and the part dressed antiseptically. The joint as diagnosed before the operation was almost completely divested of cartilage, both the aspects of the head of the humerus and of the glenoid cavity being rough and carious. Mr. Collier felt sure, however, that the case would end satisfactorily, and that fair motion and a useful joint would be obtained. His anticipations have been fully realised; the parts healed, and now (six weeks after operation) there is a fair range of motion in the joint.

It is announced that the fund formed in connection with the candidature of Drs. Langley Browne, Latimer, and McManus for the General Medical Council has been duly audited. The expenses amounted altogether to £79 10s. 8d., towards which general subscriptions to the amount of £43 10s. 8d. were received.

TRANSACTIONS OF SOCIETIES.

CLINICAL SOCIETY OF LONDON.

Meeting held Friday, January 11th, 1907.

The President, Mr. Clutton, in the Chair.

CASE OF ABSCESS OF THE LUNG AND ACUTE ENDOCARDITIS IN ACUTE PNEUMONIA.

Dr. Francis H. Hawkins (Reading) read notes of a case of this nature. The patient was a man, æt. 51, who had pneumonia of the right upper lobe which ended by lysis. After the temperature had been normal for a few days it gradually rose for ten days, then suddenly went up to 105° and fell to 102°, when the patient broke out in a profuse perspiration. The following day he had a rigor and the temperature rose to 104°, then fell to 96°, and he again perspired profusely; two days later the patient became comatose and died. No pus was expectorated throughout. At the necropsy the right upper lobe was in a state of grey hepatisation and contained three abscesses varying in size from a walnut to a hen's egg. All were lined with a distinct lining membrane. At the base of the aortic cusp was a recent fibrous deposit which on being removed showed an ulcerated surface.

Dr. **Hawkins** pointed out the rarity of abscess as a complication in acute pneumonia, and more especially an abscess with a distinct lining membrane. He thought that acute endocarditis was not so common in acute pneumonia as some writers seemed to think. He referred to some cases where the tricuspid valves were affected. He described his case as one of endocarditis pneumonia, mentioning that Weischselbaum had demonstrated the diplococcus pneumoniæ upon the growth of the valve of similar cases as Netter had also done.

Dr. **C. Theodore Williams** had seen four cases of lung abscess in acute pneumonia; two of these were influenzal in origin. He had also seen the combination of abscess and endocarditis in this condition. He did not think the surgical prospect good in these cases, as there was no time to decide on an operation before other abscesses formed. He remarked on the peculiar pleasant cowslip odour of the sputum that in the later stages of the illness replaced the original foulness. Dr. Hawkins' patient had died in coma with symptoms very suggestive of brain abscess, and he inquired whether this had been verified.

Dr. **Hawkins** said that the brain had not been examined.

Dr. **David Forsyth** read a paper on

A FATAL CASE OF MYXŒDEMA WITH CHANGES IN THE PARATHYROID GLANDS.

The patient, a woman, æt. 58, had been gradually developing the symptoms of myxœdema for four years, and at the time she came under observation had lost much of her hair and all her teeth had fallen out. She showed marked dulness and apathy, her mind wandered, and she was noisy. The skin was dry and harsh and the hands spade-like. A fortnight later she died in spite of the administration of dried thyroid gland. *Post mortem* the thyroid presented the sclerotic changes typical of the disease, and the six parathyroid glands which were found all showed certain departures from their wonted structure. These changes consisted in a marked tendency for their cells to form vesicles lined by cubical epithelium, an exceptionally profuse secretion of colloid which not only filled the follicles but lay among the masses of cells, and also distended the lymphatic channels, an abnormal increase in the connective tissue which formed coarse trabeculæ and even penetrated between the cells, and a thickening of the tunics of the arterial walls. The two former changes represented an excessive activity of the glands, and were to be regarded as an attempt on their part to supply the deficiency of colloid left by the atrophy of the thyroid, while the alterations in the stroma and arteries were probably pathological, being allied to the fibroid changes in the thyroid. The case was the first of the kind in which the condition of the parathyroids had been observed.

Mr. **W. L. Harnett** said that he had examined a large number of parathyroids and agreed with Dr. Forsyth in interpreting the presence of colloid as indicating undue activity. He was able always to correlate changes in the oxyphile cells of the parathyroid with this, and inquired as to the condition of these cells in the present case.

Mr. **Walter Edmunds** referred to the imperfect state of our knowledge on the subject. The results of experimental work with the lower animals were very contradictory. If both thyroid and parathyroid were removed from dogs, the animals usually died, but 4 or 5 per cent. suffered no ill effects, and in the case of goats and guinea-pigs also no ill effects followed. In the cases that recovered no traces could be found of any gland that might have escaped removal. He thought that work on the secretory nerves might afford a prospect of yielding useful information. He inquired as to the cause of the thyroid fibrosis in the present case, and particularly as to the existence of any evidence of tuberculosis.

Dr. **Forsyth**, in reply, said that the oxyphile cells showed changes, and were scattered uniformly, not in clumps as in the normal gland. There was no evidence of any active tuberculosis in his case, but there was a calcified focus at the apex of one lung. He referred to experiments which showed that no effects followed the secretion of the secretory nerves on one or both sides.

THE ASSOCIATION OF TETANY WITH DILATATION OF THE LARGE INTESTINE IN CHILDREN.

Dr. **Frederick Langmead** read the notes of three cases of this nature.

Case I.—was that of a boy, æt. 6, who between November, 1903, and April, 1905, was admitted five times into the Hospital for Sick Children, Great Ormond Street, under the care of Dr. Garrod, suffering on each occasion from an attack of tetany.. Each attack was accompanied by the evacuation of yeasty pultaceous stools and distension of the abdomen. Abdominal examination revealed the presence of a large hollow viscus on the left side. All treatment was ineffectual until lavage of the large intestine by means of a rectal tube was resorted to, when on each occasion improvement leading to recovery was initiated. The last attack was complicated by fatal diphtheria. *Post mortem* the hollow viscus was seen to be the sigmoid flexure which was very dilated and occupied the greater part of the left half of the abdominal cavity. It held about 13 oz. of fluid.

Case II. was that of a boy, æt. 3 years and 2 months, who was admitted on May 10th, 1906, also under the care of Dr. Garrod, for his fourth attack of tetany. This proved to be accompanied, as in Case I., by the passage of pultaceous motions, and the presence of a large hollow viscus in the abdomen. Lavage was temporarily successful, but a month after admission, diarrhœa and rapid wasting began, and operative treatment was employed. Mr. Lane removed 10 ins. of dilated sigmoid flexure, and at first the child became better. Death, however, occurred twelve days after. *Post mortem* the remaining large intestine was found to be enormously dilated, the walls being thin and atrophic, and no obstruction being present.

Case III. was that of a girl, æt. 2½, who was admitted under the care of the late Dr. Sturges, in June, 1884, for repeated attacks, associated with abdominal distension, and offensive undigested motions. She was an emaciated child, and continued to waste, and died from a terminal broncho-pneumonia. *Post mortem* the only lesion found except broncho-pneuomnia was a dilated transverse colon.

He referred also to a case reported by Dr. Batty Shaw, and Mr. Mant, in *Clin. Soc. Trans.*, Vol. 39. It was that of a girl, who for four years had suffered ulcers of the bladder. On the right side there was tuberculosis of the testis, the prostate was healthy. The left kidney was extirpated, and the ureter taken special care of, by being implanted into the psoas muscle. The right testicle was then removed. As treatment of the tuberculous condition of the bladder a mixture containing calomel in suspension was injected into the bladder, after which iodine was given internally. After some months a cystoscopic examination showed that all the ulcers of the bladder had healed. In three months the patient had gained over 20 lbs. in weight. When he attempted to return to work, however, trouble began in the other kidney, and on examining this tubercle was observed over the papillæ. Installation of the calomel mixture was used as in the bladder, and the patient had now been free from trouble for a long time.

At the Freie Vereinigung der Chirurgen, Hr. Hildebrandt reported a case of

Rupture of the Hepatic Duct.

A child, æt. 4, had been run over by a carriage. Immediately afterwards the child vomited, but the next day it was apparently well. Then, however, the condition became worse, and the patient was brought into hospital. The abdomen was distended, and tender everywhere on pressure ; and in the lower part there was dulness that disappeared on change of position. Pulse 120, no fever. The stools normal in colour ; no vomiting. During the next few days rapid emaciation was observed. The abdomen also far more distended, the temperature rose to 38° and 38.5°, whilst the other symptoms remained unchanged. There was no jaundice, but bile colouring matter appeared in the urine. On the tenth day after the accident laparotomy was performed. In the abdominal cavity " gold clear " bile was found, and numerous fibrous deposits on the intestines. The region of the gall bladder was exposed. This was normal, but a longitudinal rent was found in the hepatic duct. The attempt to close it by suture did not succeed, and nothing remained but to drain. Rapid recovery took place, and in four weeks the child was well again.

The case was a typical one of rupture of the bile passages, and it showed that laparotomy in such cases should not be delayed too long, as in a few weeks so many adhesions take place in the abdomen that any operation that must be performed is attended with much more risk than if operated on early.

Hr. Bessel related a case in which there was not only rupture of the hepatic duct, but also a double rupture of the colon, a tear in the gastro-colic ligament, and rupture of the kidney. The patient, who was extremely collapsed, was only operated on on the second day. The rent in the colon was kept closed by prolapse of the mucous membrane, bile streamed continuously out of the rent in the bile passage. As this could not be closed by suture, a drain was inserted. Notwithstanding the severity of the injuries, the patient recovered.

Hr. Hildebrandt also related a case of

Rupture of the Ureter.

A man fell from a scaffolding at the height of the second storey of a house. He fell on his right side and at once felt pain. A tumour formed near the right kidney, which at first became smaller, but began to grow again in a few weeks ; there were also vomiting, pain and a feeling of fulness in the abdomen. After three months a tumour the size of a man's head could be felt of firm elastic consistence. The urine which at first contained blood became clear. The left ureter permitted a sound to pass easily, but in the right an obstruction was met with. The cyst was opened up by nephrotomy ; it was firmly adherent to the peritoneum, so that it was not possible to dissect it from it. The right ureter was torn transversely across, and there was an opening in the pelvis of the kidney. The kidney, which was very atrophic, was extirpated, the sac, which could only be extirpated in part, was drained, and the wound with the exception of the drain opening was closed. Recovery.

AUSTRIA.

Vienna, Jan. 13th. 1907.

Osteitis Syphilitica.

Lang brought a case of osteitis of the cranium before the members of the Gesellschaft, where a gumma had eaten through the bony structure in 1903. After two sittings under chloroform the necrosed portions of bone were removed and the wound subsequently healed. The brain substance is now covered over with a thick tense membrane, through which the pulsations of the brain can be felt. Soon after the operation he returned to work, the result of the operation causing no inconvenience.

Foreign Body in Bronchus.

Kahler presented a 4-year-old child from whom he had removed a bean from the right bronchus assisted by the bronchoscope. The bean was early observed to be firmly impacted in the right side immediately below the separation to the right and left, and covered with a thin flap of membrane lying over from the left side. With a pair of long forceps the bean was seized and extracted. Kahler has had 90 of these cases, and has successfully treated 50 per cent. by this means, but the others had to have tracheotomy performed.

Tetany and Adrenal Bodies.

Königstein reminded the members of a case he showed them half a year ago where the adrenals were found in a morbid condition, and which he then associated with the tetany present. He was now able to confirm this with another case which he would show them where the adrenal bodies only showed the morbid change present at the *post-mortem*.

The child was nine months old when received into hospital suffering from well-marked symptoms of tetany. The adrenal bodies when examined in the *post-mortem* room with the naked eye, or when tested with hæmatoxilin-eosin showed no changes in the organ, but when a small portion was examined under the microscope the same results were obtained as in the former cases. In the cells a large quantity of the substance dyed like glycogen. The cloudy condition in this case was not so intense as in the former one, but sufficiently distinct to confirm his earlier opinion on the subject that the cortex and not the glandular substance was the cause of tetany.

Myxo-Idiocy.

At the Gesellschaft for Innere Medicin, Lateiner presented two children, a boy æt. 3½ and a girl æt. 4½ years, the result of consanguinity. They measured 86 and 88 centimeters and weighed 13.80 and 14 kilogrammes each. The girl had all the symptoms usually associated with myxœdema, such as lipomatous growths on the shoulders and abdomen, while the boy had more marked mucous changes. Both children had a decided increase of the thyroid gland horizontally below the larynx. In the boy's case a round swelling like a plum having the consistence of a lipoma could be felt. These cases were pointed out as uncommon in the literature of myxœdema, and added a new feature to congenital myxo-idiocy. Rosenberg remarked that the same condition often arose when the gland was rudimentary, and might be designated the hypoplastic form, as they had all the myxœdemic symptoms in proportion to their smallness.

Infantile Giant.

Knoepfelmacher showed a child, æt. 6, 146 ctms. long, the upper extremities 57, and the lower extremities 67 ctms. in length. ; the hand was 15 and the foot 16 ctms. long. The whole skeleton was of great size and well proportioned. The muscles were strong and firm like an adult, and the genitals enormously developed, as at puberty, although the child was an imbecile. Zappert had recently one very similar, which he treated with ovarian tablets with astonishing results. The brain and functions of the body rapidly improved, and the giant growth was checked.

Indigo-Uria.

Hecht recorded the history of a case, where the urine was perfectly green when newly passed, and had an indigo reaction with chemicals. According to the *post-mortem* by Wang, the oxidation seemed to have taken place in the kidney, as he could find little colouring of blue in the sections of the diseased organ.

FROM OUR SPECIAL CORRESPONDENTS AT HOME.

SCOTLAND.

Annual Report of the Edinburgh Royal Infirmary.—During the year ending, 10,430 patients were admitted, the total number under treatment being 11,216, an increase of 200 as against last year. The average duration of treatment was 27.7 days, as compared with 28.3 in 1904-5. The percentage of deaths was 7.36, or, deducting those which took place within forty-eight hours of admission, 5.75, an increase of .04. During the year 37.235 out-patients attended the various departments of the infirmary. The total ordinary income was £33,695, and the ordinary expenditure £52,116, being £1,972 more than last year. The increased expenditure is accounted for by a rise in the number of occupied beds from 828 to 839, by the additional staff required to conduct the new surgical out-patient department, by the staff required for massage, and by the telephonic staff, and the growing use of the electrical department. Among the changes and additions during the year are the provision and equipment of a new electrical and a new bath department, the substitution of paid for unpaid nurses under the longer period of training, the reorganisation of the pathological, fire, and works departpartment. Among the economies effected have been a reduction in coal consumption, in maintenance and in medical expenditure, and cleaning. The legacies and donations for the year totalled £22,670, and the extraordinary expenditure reached £14,352—plumbing and new drainage, operating theatres, and surgical out-patient department being the main items. It is proposed to appoint an organising secretary for subscriptions whose time shall be devoted to stimulating interest in the Royal Infirmary. The reconstruction of the incidental delirium and medical out-patient departments have been under the consideration of the managers, but have been delayed for a year owing to more urgent matters demanding attention.

Rectorial Addresses in Edinburgh and Glasgow Universities.—The event of the week in the two sister Universities has been the delivery of the customary rectorial addresses. Of late years it has too often been the case that such occasions have afforded the rowdy elements of studentdom full scope for an exhibition of noisy horseplay, but this year a better order of things reigned, and the whole proceedings were unmarred by the slightest disturbance. It is to be hoped that the tradition having been reversed, the new order will establish itself, so that future Lord Rectors will deliver their addresses to audiences as courteous and appreciative as those of last week.

At Edinburgh, Mr. R. B. Haldane, K.C., M.P., secretary of State for War, delivered a masterly and humorous address on "the dedicated life," the theme being the duty which citizenship involves of directing the energies of the State towards great ethical ideals. He dwelt on the power of individuality, and on the function of the Universities in training thinkers who could plan and organise, who could carry out well-considered schemes for the advancement of humanity. As an illustration he took the case of Germany when she lay crushed after Jena, and showed how through the exertions of the galaxy of profound thinkers in Berlin, Jena and Weimar, the conception of the State was reconstructed, education, the key to all advance, was reorganised, and the military problem was solved. The labours of these men permeated the whole German people, and blossomed into full fruition after seventy years. After delivering his address, Mr. Haldane inspected the University Volunteers, and was subsequently entertained to luncheon in the University Union. The proceedings terminated in a torch-light procession.

Mr. Asquith was installed as Lord Rector of Glasgow University on January 11th, and addressed the students on "Ancient Universities and the Modern World." Of the origin of Universities, he spoke especially of their cosmopolitan and Catholic nature, and of their object in developing knowledge for its own sake, without, however, dividing it from practice; the steam engine and "The Wealth of Nations" were the most magnificent presents statesmen, financiers, and industrialists had ever received, and both came to them from within the walls of Glasgow College. The main topic of his address was the value of properly directed literary and historical studies; for instance, no more valuable lesson could be learned than from the study of the golden age of Rome. The best gift of the University to its students was the power, in after years, when they were immersed in the practical work of life, of keeping the windows of the mind and soul open to air and light.

After the address, Mr. Asquith attended a smoking concert given in his honour, and then drove to Queen Margaret College, where he addressed a few words to the women students.

BELFAST.

TUBERCULOSIS IN PIGS.

A case of considerable interest and importance was in the Custody Court of Belfast last week, when a firm of provision dealers sued the Corporation for £4 3s. compensation for the carcase of a pig seized by a Corporation official and destroyed by order of a magistrate, on account of the presence of tubercle. The interesting point is that the evidence of the disease was confined to the submaxillary glands, all the internal organs having been removed in the country, where the animal was killed, before bringing the carcase to Belfast for sale. The question at issue was whether a small spot of diseased tissue in a gland justified the destruction of the whole carcase, and of course in Belfast, where thousands of pigs are converted into ham and bacon every week, the question is of great importance. The obvious reply is that a more thorough inspection of the whole carcase should be made before the internal organs are removed. But unfortunately under present methods of working this would cost more than the value of the animal. The same difficulty does not arise with the carcases of cattle and sheep, for the whole animal is presented for sale, nothing being removed, and a complete inspection is easily made. The Bench dismissed the case on its merits, and were prepared to state a case.

LETTERS TO THE EDITOR.

FREE OR SOBER.

To the Editor of The Medical Press and Circular.

Sir,—May I venture to draw your attention to a serious and growing abuse? Many of your readers will remember how a famous Bishop of Peterborough once expressed the opinion that, for his part, he would rather the people should be free than sober, and it is, at any rate, becoming more and more evident that it is impossible by any practicable amount of coercive legislation to prevent a tolerably free people from getting drunk if determined so to do. This fact is being well brought out in a series of admirable articles in the *Times* on the licensing question. The crusade against drink and the public-house has led to an enormous increase in drinking clubs. A nominal subscription constitutes membership; the frequenters can stay and drink as long as they please, and can even be accommodated for the night if too drunk to leave. Then, again, in many towns the sale of spirits and bottled beer for consumption at home has increased enormously and women who dare not for shame frequent the public-house meet together to indulge in alcoholic drinks instead of tea. The chemists do a large trade in "nips," and in some places it is certain that these nips are often composed of vile substances such as methylated spirit. The *Times* does not speak of the enormous trade in "tonics" advertised under various fanciful names, and all alike containing a large percentage of alcohol. Although often described as made from fine wine, there can be no doubt that these preparations are too often merely concoctions of rude alcohol, sweetened, flavoured, and made pleasant to the taste. These appeal to women secret drinkers above the poorest classes. Such women can, without shame, obtain from the chemist supplies of their favourite "tonic," although they dare not send for or openly purchase a bottle of wine or spirit from a public-house or a dealer. Many women become habitual drunkards from being gradually led on to find solace in bogus tonics containing alcohol, and within the past few weeks there was notified the death of a lady, a prominent professed active teetotaler, in which the autopsy demonstrated alcoholic disease of the liver. It was elicited in inquiry that she had for a long time been in the habit of dosing herself with a certain "tonic," whilst ignorant of the fact that it contained a large proportion of alcohol. This illustration is sufficiently suggestive of the harm in so many different directions that the unrestricted trade in fraudulent quack medicines is inflicting upon the people.

I trust that the subject may give rise to a correspondence in which the views of your medical readers may be freely expressed. The time is ripe enough, in all conscience, for such a discussion.

I am, Sir, yours truly,

H. S.

SERUMS, VACCINE, AND HOMEOPATHY.

To the Editor of The Medical Press and Circular.

Sir,—If it is not too late to comment on some editorial remarks in your issue of December 26th, I shall be obliged if you will allow me a little space. The Christmas holidays put me in arrears with my journals, or I should have taken the opportunity earlier.

In your note on the annual meeting of the British Homeopathic Association, you say:—"It is entertaining to read that the present-day use of serums, vaccines, and emulsions brings the rest of the profession nearer to homeopathy." And you add:—"We remember some time ago a homeopath claiming diphtheric antitoxin for their own."

I think, sir, you will allow that if there are two men living who know more about diphtheria antitoxin in particular, and serums in general, than anyone else, these two men are Dr. Roux and Professor von Behring. It is on record that Dr. Roux has admitted that "there is truth in the Hahnemann method of curing likes with likes." And now Von Behring has published a statement which confirms this, and shows that it is the Seropaths themselves—if I may use the word—rather than the homeopaths who are proclaiming that the new practice is really homeopathy, with the infinitesimal dose thrown in. In his recent work (1906), entitled "Modern Phthisio-genetic and Phthisiotherapeutic Problems in Historical Illumination," Von Behring, speaking of the tuberculin treatment of phthisis, says the "scientific principle" of it is not established, but:—

"In spite of all our scientific explanations and experiments regarding small-pox vaccination, Jenner's discovery remained an erratic block in medicine till the biochemically thinking Pasteur, devoid of all medical class-room knowledge, traced the origin of this therapeutic block to a principle which cannot be better characterised than by Hahnemann's word, 'Homeopathic.'

"Indeed, what else causes the epidemiological immunity in sheep, vaccinated against anthrax, than the influence previously exerted by the virus, *similar* in character to that of the fatal anthrax virus? And by what technical term could we more appropriately speak of this influence, exerted by a *similar* virus, than by Hahnemann's word, 'homeopathy'?

"I am touching here upon a subject anathematised till very recently" (I fear, sir, the present might also be included)—"by medical pedantry; but if I am to present these problems in historical illumination, dogmatic imprecations must not deter me. They must no more deter me now than they did thirteen years ago, when I demonstrated before the Berlin Physiological Society the immunising action of my tetanus antitoxin in infinitesimal dilution. On this occasion I also spoke of the production of the serum by treating animals with a poison which *acted the better the more it was diluted*" (italics mine), "and a clinician, who is still living, remonstrated with me, saying that such a remark ought not to be made publicly, since it was grist for the mill for homeopathy. I remember vividly how Dubois-Reymond, who during the progress of the demonstrations and discussions had become drowsy, suddenly sat up all attention when I replied in almost these words:—'Gentlemen, if I have set myself the task of rendering an incurable disease curable by artificial means, and should find that the road of homeopathy led to my goal, I assure you, dogmatic considerations would never deter me from taking that road."

I think, sir, you will admit that homeopaths have plenty of outside justification for the claim they make, a claim which seems to have caused you some entertainment.

I am, Sir, yours truly,

John H. Clarke.

8, Bolton Street, W., January 13th, 1907.

NOTES AND COMMENTS.

To the Editor of The Medical Press and Circular.

Sir,—The readers of The Medical Press and Circular no doubt appreciate the attention that is given in your journal to those questions which deal with the various delusions and humbugs, more or less fraudulent, to which an imaginative and ignorant public is exposed at all times in matters medical. In this week's Medical Press and Circular four out of the eight articles deal with questions of medical humbug: "Quacks and Patent Medicine Vendors," "A Bonesetter's Challenge," "Hospital Abuse, &c.," and "Dr. Doyen's Cancer Serum," are each of them subjects which in your opinion require attention. Under the heading "Notes and Comments" the part played by "a well-known monthly medical journal" is the subject of comment, as the conduct of proper practitioners is fairly criticised by you. Your remark that "the patience of the general practitioner is nearly exhausted" in regard to hospital abuse may be extended in many directions, and special contributions might be made by your readers and others in this class of subject under the special heading of "Notes and Comments," and which would have far more effect than the work of any Royal Commission.

It was painful to read the report of that meeting at which the Hon. Sydney Holland charged Sir Henry Burdett with wilful mendacity. It is needless to make any remark upon this occurrence, except that it is probable it would not have occurred at a meeting of only qualified professional men. Their sense of mutual regard and respect is happily more cultured than among some men, when engaged in discussion.

I am, Sir, yours truly,

One of your Readers.

OBITUARY.

JAMES ROSS, M.D.

We regret to announce that Dr. James Ross, physician and surgeon in the Clitheroe district, died early on the 5th inst. at his residence, Meadow Bank, Chatburn, aged fifty-five years. The cause of death was pneumonia, and the end was somewhat sudden. He was a well-known medical gentleman throughout North-East Lancashire, having formerly practised in Burnley. He leaves a widow and five children. Deceased was medically educated at Queen's College, Belfast, whence he graduated M.D.R.U.I. in 1874.

SURGEON-GENERAL RICHARD CHAPMAN LOFTHOUSE.

THE death is announced of Surgeon-General Lofthouse, at the age of 74, on January 10th at Harrogate. Appointed an assistant surgeon in July, 1854, he served with the 10th Hussars in the Crimea from April, 1855, his service including the siege and fall of Sevastopol, the battle of Tchernaya, and the affair near Kertch. Joining the 14th Light Dragoons in India in 1857, he served through the long operations of Sir Hugh Rose and Sir R. Napier in the suppression of the Sepoy revolt in 1858 and 1859, including the sieges of Rahutghur and much other active service. He was mentioned in despatches and thanked by the Director-General Army Medical Department. He was promoted surgeon in 1867, surgeon-major in 1873, and deputy-surgeon-general in 1884, in which year he retired.

SPECIAL ARTICLE.

LUNACY IN IRELAND.

THE annual report of the Inspectors of Lunatics for Ireland (a) hardly attracts as much interest as usual, on account of the recent publication of a Supplementary Report dealing with the Increase of Insanity in Ireland. It is stated that there were on January 1st, 1906, 23,365 lunatics within the official knowledge of the Inspectors. This shows an increase of 369 during the year, as against 202 in the previous year. The decrease in the number of lunatics in workhouses has continued, so that the number in these institutions is now the lowest during the past twenty-five years. Only 14 per cent. of the total number of lunatics are now in workhouses, whereas the proportion in 1880 was 27 per cent.

Instructive tables are given, showing in series of numbers of lunatics under care, and the proportion per 100,000 of the population, for each year since 1880. The actual number of insane under care has increased from 12,982 to 23,365, and the proportion per 100,000 of the population from 250 to 532. If to the number of insane under care on December 31st last be added the number of lunatics and idiots at large according to the last census, the total (27,233) represents 620 per 100,000 of the population, or one person of unsound mind in every 161 of the population.

Although the number of insane persons has shown a steady increase, there has been since 1903 a slight falling off each year in the number of admissions to asylums. The respective figures for 1903, 1904, and 1905, are 3,950, 3,910, and 3,772.

The total number of patients discharged during the year was 1,876, viz., 1,022 males and 854 females. Of these 1,389 (722 males and 667 females) were discharged recovered; showing a decrease of 29 on the number for the previous year. The percentage of recoveries on the admissions was 36.8, being .5 per cent. higher than that for the previous year.

The number of deaths during the year was 1,450, of which 809 were males and 641 females. This shows an increase of only one on the numbers for the previous year, the males having increased by 57 and the females having decreased by 56. The death-rate per cent. of the daily average number resident was 7.7, viz., 7.9 amongst the males, and 7.4 amongst the females. The general rate was .1 lower than that for the previous year—the rate in the case of the males being .4 higher, and in the case of the females .8 lower. Six of the deaths were by suicide; four resulted from misadventure; and, in two cases (a male and a female), the patients were killed by fellow-patients.

The percentage of deaths on the daily average number resident in each district asylum during the years from 1896 to 1905 is given. From this table it will be seen that the highest death-rate during 1905 was 11.2 per cent. in Maryborough, and the lowest 5.0 per cent. in Mullingar Asylum. The highest rate was 1.5 per cent. less than the corresponding rate in the previous year, which was 12.7 in the Sligo Asylum, while the lowest rate was .1 lower than that for the previous year, viz., 5.1 in the Kilkenny Asylum.

In 238 cases the cause of death was verified by post-mortem examination. Of the deaths 407 were due to phthisis, 55 to general paralysis of the insane, 30 to dysentery or colitis and diarrhœa, and 18 to typhoid fever.

The Inspectors again draw attention to the neglect of pathological research in most Irish asylums, and point out that in this respect they are far behind the more important asylums in England, Scotland, France, Germany, Italy, America, and New South Wales. They suggest that some arrangement might be come to—at all events in the more remote districts—by which a number of asylums might combine in providing a common laboratory, and in appointing a pathologist who would give instruction to the junior members of the staff, and carry out the more important investigations. Such an arrangement for the furtherance of the study of mental disease was contemplated and authorised by the provisions of Section 5 of the Act 1 Edwd. VII., cap. 17.

The financial tables should be of great value to those interested in asylum management. They exhibit —as is to be expected—wide variations, both in the cost per head of the several classes of expenditure, and in the net cost per head for maintenance. Thus the cost per head for salaries and wages among the district asylums varies from £3 17s. 8d. in Ballinasloe to £7 4s. 2d. in Londonderry; for provisions and groceries, from £6 18s. 9d. in Downpatrick to £10 9s. 11d. in Cork; for wines, spirits, and beer, from less than ½d. in Armagh to 6s. 1d. in Clonmel; for tobacco and snuff, from 1s. 10d. in Maryborough to 7s. 9d. in Kilkenny; for medicines and appliances, from 7d. in Antrim to 6s. 7d. in Cork; for clothing, from 15s. 8d. in Carlow to £3 3s. 1d. in Mullingar; for fuel and light, from £1 10s. in Clonmel to £3 2s. 9d. in Mullingar. The net cost per head varies from £19 8s. 9d. in Castlebar to £26 16s. 5d. in Ennis.

Full particulars are given of the inspections of the various asylums and licensed houses.

(a) "Lunacy—Ireland." The Fifty-fifth report (with appendices) o the Inspectors of Lunatics (Ireland), for the year ending December 31st 1905. Dublin: H.M. Stationery Office, 1906. Price 1s. 1d.

REVIEWS OF BOOKS.

LINDSAY ON DISEASES OF THE LUNGS (a)

THE favourable reception of the first edition of his "Lectures on Diseases of the Chest" has given the author an opportunity of producing an enlarged second edition entirely devoted to pulmonary diseases, the lectures on heart disease which were previously incorporated being now omitted, and several new chapters on lung diseases being added. The work as it now stands is a fairly complete compendium of our clinical knowledge of lung disease, presented in an attractive and readable form, and made more interesting by the personal tone which the writer's experience enables him to add to its pages. The first four chapters are devoted to a description of the physical examination of the thorax, including a summary under each heading of the causes and conditions underlying the various abnormalities that may be revealed. Throughout these chapters the author keeps the practical examination of a patient clearly before his mind, and we are glad to notice that, while using every recognised means of examination and dogmatically stating the value of each sign where value in his opinion lies, he refuses to base definite opinions on any finical distinctions between nearly allied signs or equivocal phenomena. Thus in discussing râles and rhonchi he freely admits that our present classification is unsatisfactory, and that a "consonating râle and a crepitant râle are not usually differentiated," and further on quotes, apparently with some approval, Sahli's statement that ægophony, pectoriloquy and bronchophony cannot always be distinguished. Chapters on pulmonary symptoms, including those that are met with in other parts of the body in connection with lung disease, follow, and then a most useful chapter on the naked-eye and other characteristics of the sputum. This brings what we may call Part I. of the book to a termination, the remainder of the volume, about 450 pages, being occupied with a systematic account of the different diseases of the pleura and lung, the largest single section of this latter part being given, as might be expected, to an account of pulmonary tuberculosis in all its phases. In considering the treatment of this disease, the writer is at his best, and we recommend a careful perusal of his teaching in this respect to all practitioners. The comparative uselessness of the many treatments which are introduced yearly, such as intratracheal injections and intravenous injections, is at once stated, and thus the way is paved for a candid, thorough, and common-sense discussion of the problem. Under Pneumonia, also, a good critical account of the therapeutics of that disease is to be found, and a much-needed warning note is sounded on the question of over-feeding. In conclusion, we can cordially recommend the work, and we offer our congratulations to the author on its appearance.

(a) "Lectures on Diseases of the Lungs." By J. A. Lindsay, M.B., Professor of Medicine, Queen's College, Belfast. Second Edition, enlarged and re-written. Pp. 520. London: Bailliere, Tindall and Cox. 1906. Price 10s. 6d.

ASH ON HYPNOTISM. (*a*)

Hypnotism still remains to most medical men a subject on which judgment should be reserved. That hypnotism is an ordinary phenomenon of the mind is not now in doubt; no one believes in dual personalities except such as like picturesque explanations for things not fully understood. But that hypnotism is of so much value as to be worthy of a place alongside ordinary therapeutical methods is still questionable, and we do not think Dr. Ash's book will do much to convince those seeking assistance. The most we ever find about hypnotism is that it is a measure pregnant with possibilities, and that occasionally with a suitable subject a lucky hit is made. It is claimed that hypno-therapeutics are still in their infancy—a perfectly reasonable plea; but if hypnotism is so little understood, the responsibility of using it on the subjects of disease is not without a grave aspect. Dr. Ash deals with the technique of inducing hypnosis and gives certain practical hints; this part of the book will be useful to those who wish to launch out into experiments.

LITERARY NOTES.

We have received Herbert Fry's Royal Guide to the London Charities for 1907. As usual, it is full of well-sifted information on the subject with which it deals, and it remains as valuable as ever for the medical man who wishes to know how to deal with the various classes of poor patients which private charity cannot cope with. Fry's "Charities" is a synonym for accuracy.

⁂

The prize of £8,000 instituted by the King of the Belgians is likely to cause some difficulty in its bestowal. It was promised by His Majesty to the discoverer of a proved remedy for Sleeping Sickness, and as Dr. Vancampenhout, a Belgian scientist, is reported to have actually cured two men afflicted with the disease, he is a claimant. Dr. Koch's recent discoveries in Africa have rendered considerable service to the work of research, and the question arises, to whom shall the prize be awarded. Both seem entitled to it, and the authorities are at a loss to know to whom they shall offer it.

⁂

At the present time, when the terrible wastage of infant life is attracting so much attention, a volume which the Caxton Publishing Company announce for immediate issue will appear very opportunely. The work is by Professor Budin, the famous obstetrician of Paris University, whose lectures are well known to the readers of this journal. The work, which is translated by Dr. W. J. Maloney, with an introduction by Sir A. R. Simpson describes in elaborate detail, with numerous coloured graphs, a method of treatment which has already attained marvellous results in France in reducing infant mortality.

⁂

The "Lemco" Company are at present making an offer which will doubtless prove attractive to householders, especially such as use Lemco in their *menage*. The offer takes the form of a present of Mrs. Beeton's well-known book "Household Management," to such as send on or before March 31st next coupons representing five pounds weight of Lemco. Each jar contains a small coupon under the capsule, and it is these coupons that are to be sent. The Company have long gone on the principle that the more cooking was cultivated, the more Lemco would be in demand, and they have given away some millions of cookery books already. At present, one called "Lemco Dishes for All Seasons" can be obtained by writing name and address on a Lemco wrapper, and as it contains *inter alia* some twenty recipes for sick-room dishes it is likely to be specially useful to medical men. The address of the Company is 4, Lloyd's Avenue, London, E.C.

⁂

Among the diaries received for 1907 is the popular Wellcome's "Photographic Exposure Record and Diary," which has undergone its annual revision, no efforts having been spared to bring the information right up to date. A glance at the table of plate speeds will be sufficient to convince the reader that the compilers have lost no time in adding particulars of the latest reliable plates and films. An entirely new series of examples illustrates the article on exposure, and increases its value, and as a large number of medical men resort to photography for pleasure or for professional purposes, this will be greatly appreciated. The usual diary and memoranda pages are retained, as in previous issues, but increased space is provided for the record of negative exposures, there being now room for 336 entries. Two editions are issued as usual one for the Northern Hemisphere and one for the Tropics and Southern Hemisphere. The familiar art green canvas binding has been retained, and the price is still 1s.

A fourth edition of Hadden's "Pocket Vocabulary of Medical Terms" has just been published by Messrs. Hadden, Best, and Co., revised by Dr. Philip Cowen and Mr. Herbert Davey. The book is intended for the use of registrars, poor-law officials, and others who in the course of their business have to deal with medical terms. The volume has been brought thoroughly up to date, and is now the best book of its kind in the market.

⁂

A dainty booklet, entitled "A Few Hints on the Care of Children at Sea," reaches us from Messrs. Bale, Sons, and Danielsson. It is written by Dr. Samuel Synge, and gives, within the compass of thirty pages, many useful suggestions which mothers and nurses are sure to appreciate. The price of the booklet is one shilling net, and medical men who have patients going on a voyage will find this a useful guide, as it is full of valuable hints which only a writer with experience of such matters can give.

(*a*) "Hypnotism and Suggestion: A Practical Handbook." By Edwin Ash, M.B., B.S.Lond., M.R.C.S., sometime Demonstrator of Physiology in St. Mary's Hospital Medical School, &c. London: J. Jacobs. 1906. 4s. net.

WEEKLY SUMMARY OF MEDICAL LITERATURE, ENGLISH AND FOREIGN.

Specially compiled for THE MEDICAL PRESS AND CIRCULAR.

RECENT GYNÆCOLOGICAL LITERATURE.

Use of Intercutaneous Stitch in Plastic Operations on the Perineum.—Anspach (*Amer. Jour. of Obst.*, December, 1906). The intercutaneous stitch had given such excellent results in cœliotomy wounds, the writer began to use it in posterior colporraphy operations. The usual Hegar or Emmet's operation is performed up to the insertion of the external sutures, and then these external sutures are introduced and brought out just within the skin borders of the denudation. After these sutures are tied, the intercutaneous (subcuticular) stitch is employed, running from above downward. The advantages claimed are as follows:—The crown sutures are buried, catgut may be used, and the pressure necrosis and the pitting of tissue commonly observed are entirely avoided. F.

Prolapsed Ovaries.—Gardner (*Amer. Jour. of Obst.*, December, 1906). A very large proportion of prolapsed ovaries occur in association with retrodisplacements of the uterus, and when we take into consideration the frequency of retrodisplacements, and the fact that about 25 per cent. of them are congenital, one of the most prolific causes of prolapsed ovaries is accounted for. The direct cause of the prolapse, both in cases associated with retrodisplacements, but more particularly in those in which the uterus maintains a normal position, is the elongation of the ovarian ligament. Another condition found is that nearly all prolapsed ovaries are enlarged, either as a cause or result. The symptoms complained of are pain in the pelvis in one or both ovarian regions, at times radiating down the legs, and invariably increased by the patient being on her feet; pain in sacral region, radiating upwards, and associated with paroxysmal occipital headache is very common. A very characteristic symptom is a severe paroxysmal intermenstrual pain in the pelvis. Dysmenorrhœa is usually severe, and usually begins before the flow, and lasts till a day or more after it has ceased. In nulliparæ it usually dates from the beginning of menstruation; in those who have borne children from some time subsequent to the last confinement. Nervous symptoms, painful coition and defœcation are also common. The writer next mentions the treatment by means of vaginal tampons and pessaries, by shortening the infundibulo-pelvic ligament, by stitching the ovary to the peritoneum at the pelvic brim, by bringing the ovary through an opening in the broad ligament, and fastening on the anterior surface, and, lastly, mentions shortening of the elongated ovarian ligament by a couple of fine silk stitches passed between the ligament near the ovary and the back of the uterus close to its junction with the other end of the ligament, as the treatment he has found most successful. If there is an associated retrodisplacement the operator can then proceed to do the operation of choice for its correction. F.

Contraction and Shortening of the Utero-Sacral Ligaments: A Suggestion as to Etiology and Treatment.—Craig (*Amer. Jour. of Obst.*, December, 1906). This paper embodies the results of personal observation in a certain number of cases of such a character as to lead the writer to consider the results worthy of confirmation or refutation by others. In a certain proportion of the cases in which the utero-sacral ligaments are found contracted, thickened and sensitive to the touch, they are so as the result of an active contraction of their muscle fibres, the object of which contraction is solely the defence of an inflamed cervix, aiming to draw it upward and there fix it, so lessening its irritation by the ordinary bodily and respiratory movements and minor traumatisms. This defensive contraction usually is found in connection with one particular form of cervical inflammation, namely, endotrachelitis. Why it does not occur in all cases of swollen, eroded, lacerated cervices the writer has been unable to determine, unless it be due to the fact that such conditions are not usually sensitive nor easily affected by traumatisms of a minor degree. If this contraction of these ligaments is merely the symptom of an endotrachelitis, when this condition is cured the contraction should subside, and here the writer quotes a case to bear out the statement. His treatment of the cervix consists of curettage in accordance with the technic and with the instruments described in a paper in the *New York Med. Jour.*, January, 1906. F.

Pubiotomy and its Relative Indications.—Moutgomery (*Amer. Jour. of Obst.*, December, 1906). The history of pubiotomy is directly connected with that of symphysiotomy, from which procedure it has been evolved, and over which it now seems to be a very distinct improvement. Gigli, in proposing the substitute in 1894, sought to present a linear osteotomy made through the pubic bone at a point where the soft parts would be less liable to damage, and permitting of the same pelvic enlargement as the older procedure. The lack of union and defective gait he has sought to replace, and bring the risk of wounding the bladder and clitoris to a minimum. The superior results obtained, as shown by statistics produced by the writer and Dr. Gigli, have won enthusiastic support for the procedure from Doderlein, Duehrsen and others in Germany, and the technic of the operation has been variously modified by them. In a few years it will be found that the Gigli wire saw and carrier will almost entirely replace the use of craniotomy instruments, the latter being reserved for use only on the dead child. An indication, other than contracted pelvis, for the performance of pubiotomy is the occurrence of an impacted mento-posterior face presentation in which a change of position cannot be effected by the Volland or other procedures. Pfannenstiel has advocated the use of this operation along with the production of premature labour at about eight to eight and a half months. With regard to the technic, the procedures divide themselves into three groups—the open method, the partly subcutaneous, and the wholly subcutaneous. The after treatment is exceedingly simple; a strip of adhesive plaster encircling the pelvis has proved sufficient for immobilisation in most cases. F.

The Employment of Scopolamine and Morphia During Labour is considered by Lehmann (*Zeitsch. für Geb. und Gyn.*, Bd., LVIII., Hft. 2), who used it in 70 chosen cases, the women all having normal labour. The first injection was given as soon as strong painful contractions set in, and was repeated when painful contractions again made themselves evident, but this had never to be done for at least an hour. Sometimes after another three hours a third injection was required. The dose each time consisted of scopolamine hydrobrom. 0.0003, with morph. mur. 0.01 dissolved in 1g. of distilled water. Forty-five women received two injections, thirteen three injections, and twelve, owing to the rapidity of their delivery, only one injection. The labours lasted from one to forty-three hours. As regards the influence over the pain, the labour in 61.6 per cent. of the cases was completely painless, in 37 per cent. the suffering was very much relieved, and in only 1.4 per cent. it had no effect. 13.3 per cent. of the children were born in a state of asphyxia, 10 per cent. had very shallow respiration, and the remaining 76.7 per cent. were perfectly normal. The proportionately large number of children born in asphyxia must be considered the result of poisoning of the ovum from transmission of the drugs through the placental circulation. As regards the effect upon the strength of the contractions, the results are exceedingly favourable, since weak pains were only observed in 16.3 per cent. of the cases. In 25 per cent. the labour was accelerated, and in 58.7 per cent. the power of the contractions was quite unaltered. The author comes to the conclusion that this method must be regarded as a most important addition to our means of relieving or removing the suffering during labour, but its great disadvantage lies in the increase of asphyxia of the infants. Its employment should therefore be restricted for the present. G.

The Lower Uterine Segment.—Aschoff (*Zeitsch. für Geb. und Gyn.*, LVIII., Hft. 2) says that all the many different opinions on the lower uterine segment are due most of all to the fact that the various authors wish to recognise the cervix as being different from it, and that the exact boundaries of the lower uterine segment have not yet been defined. In opposition to the macroscopical division of the uterus into two parts, the corpus and cervix with the frontier at the internal os, it must be considered, from the microscopical examination, as consisting of three parts: the body of the uterus, with its distinct corporeal mucous membrane, the upper third of the cervical canal, which is lined with mucous membrane resembling that of the body, and which the author calls the isthmus, and the lower two-thirds lined with typical cervical mucous membrane—the cavity of the cervix. The body of the uterus and the isthmus are divided from one another by the orific. int. anatomicum, the internal os of the uterus according to the old definition, and the isthmus and cavity of the cervix by the orific. int. histologicum—the internal os of the cervix. Among these three parts of the uterus the isthmus is the lower uterine segment. When pregnancy occurs the body of the uterus is completely taken possession of for the accommodation of the ovum and the isthmus also to a varying degree. The upper border of the lower uterine segment, the contraction ring, corresponds to the internal os of the uterus, and the lower border in the majority of cases lies just above the internal os of the cervix, that is the boundary between the cervical mucous membrane, and the mucous membrane resembling that of the body. G.

Vaginal Hysterectomy for Total Prolapse of the Uterus.—Kirchgessner (*Zeitsch. für Geb. und. Gyn.*, Bd. LVIII. Hft. 2) says that this operation, in combination with a plastic operation on the vagina, when such was required, has been performed on forty women in the Würzburger Frauenklinik from 1892 to April, 1905. Three women died in the hospital after the operation, but only one death could be looked upon as the direct result of the operation. As regards the permanency of the cure, it was possible to keep thirty-two cases under observation, twenty-six of them being examined from time to time in the hospital. In twenty-six cases, *i.e* 81.25 per cent., permanent cure resulted; in four cases, *i.e.* 12.3 per cent., there was a partial recurrence, and in two cases, *i.e.* 6.25 per cent., there was a large recurrence. Several months to eleven years had elapsed since the operation In the majority of the cases the ages of the patients were between 45 and 65. G.

A Classical Case of Chorio-epithelioma Malignum is recorded by Czyzewicz und Nowicki (*Monatssch. für Geb. und Gyn.*, Bd. 24, Hft. 4). The patient, æt. 27, had aborted four months before they saw her, and had been bleeding continually since. The uterus on examination was found to be about the size of a man's fist, soft like dough, and not painful. The internal os was closed. There was considerable bleeding; the right ovary somewhat enlarged. Shreds of soft tissue were removed by the curette, and microscopically thev increased the suspicion that it was a malignant growth. The bleeding continued. The patient was again curetted, and as the bleeding did not then stop, the removal of the uterus was decided upon. Before this was done the patient had a severe attack of internal hæmorrhage, which compelled an immediate laparotomy. The hæmorrhage was now found to be coming from a small perforation of the enlarged ovary. Owing to the serious condition of the patient, the ovary alone was removed. Microscopical examination of it revealed chorio-epithelioma malignum. The immediate extirpation of the uterus was, of course, now decided upon, and again before it could be done the patient developed a right-sided croupous pneumonia, which, however, ran a normal course. The uterus was then removed per vaginam. The patient recovered very well at the beginning, then she got an attack of hæmoptysis, and one month later she died from gradual loss of strength. The autopsy revealed a dissemination of the chorio-epithelioma throughout the whole body. From this case the authors come to the conclusion that the microscopical diagnosis of a chorio-epithelioma malignum may in some cases present practically unsurmountable difficulties, and that in such cases one should not always demand an exact microscopical diagnosis before hysterectomy is decided upon. The clinical symptoms are of much more value. The authors conclude as follows:—(1) Malignant chorio-epithelioma grows and extends itself so rapidly that it may cause severe internal hæmorrhage. Probably the metastases grow more quickly than the mother tumour. (2) An intrauterine tumour which is not broken down, and which has a smooth surface, may remain unnoticed during curetting. (3) The clinical symptoms are of the most importance in the diagnosis of malignant chorio-epithelioma. A doubtful or negative microscopical result is not significant. (4) The internal genital organs must be removed by laparotomy, not through the vagina, as early as possible. G.

Total Prolapse of the Uterus in the 16th Year.—Sutter (*Monatssch. für Geb. und Gyn.*, Bd. 24, Hft. 4) records the case of a nullipara 18 years of age, who three years before he saw her got prolapse of a small portion of her vagina while doing some heavy work. This gradually became larger, and in twelve months had developed into a complete prolapse. On examination he found the patient badly nourished and anæmic. There was total prolapse of the vagina, and in it could be felt the round ligaments, the ovaries, and the small retroflected uterus. He amputated the hypertrophied portio, did an anterior colporrhaphy, and an Alexander-Adams operation. In four weeks there was a recurrence consisting of prolapse of a small portion of the posterior vaginal wall. The vagina had again become very wide, the uterus somewhat descended, but had remained well anteflected. Posterior colporrhaphy was performed, and by pulling the tissues and muscles well together a firm perineum was produced. The patient was discharged quite cured. The case is particularly interesting since prolapse at this age is so very rare. The author believes it to have resulted from the severe straining, the weak constitution, and before all the infantile state of the genitals. The combined effect of these was to produce a weakening of the pelvic floor, and the vicious circle was then completely closed by the hypertrophy of the prolapsed uterus. The prognosis in such cases is very bad. As regards treatment, the author lays most stress on the importance of making a firm pelvic floor with a particularly solid and thick recto-vaginal septum. To this fixation of the uterus must be added when there is retroflexion or the uterus is very mobile. G.

Many Years in Hospital.

Miss Ellen Elizabeth Carr, who was admitted to the Royal Hospital for Incurables, Putney Heath, in the year 1868, died the other day. after being an inmate of that institution for thirty-nine years. Although suffering from an incurable disease, Miss Carr maintained to the last a cheerful and contented disposition. At the time of her admission to the hospital it was not anticipated that she would live more than a few years. Her age at the time of her death was seventy years.

Medical News in Brief.

Royal College of Surgeons of England.

A quarterly meeting of the Council of the Royal College of Surgeons was held at the College on Thursday last, Mr. Henry Morris, President, in the chair.

The President stated that the vacancies on the Court of Examiners occasioned by the expirations of the periods of office of Mr. Wm. Watson Cheyne, C.B., and Mr. Frederic Eve would be filled up at the ordinary meeting of the Council in February, and that Mr. Cheyne did not propose to offer himself for re-election.

In reference to a letter from the Liverpool School of Tropical Medicine asking the views of the College upon a scheme for revising the course of instruction at the school, the Council expressed the opinion that so far as it relates to the subjects of tropical medicine, tropical surgery, and tropical hygiene, the scheme deserves approval. The Council also noted with satisfaction that it is proposed to afford greater opportunities for clinical observation than exist at the present time.

The Council adopted a report from the Committee of Management submitting the proposed arrangements with the London School of Tropical Medicine for the attendance of assessors from the Royal Colleges of Physicians and Surgeons at its examinations, and a further report from the same committee, which included the following recommendations, was also adopted: That Berkhamsted School, which is already recognised for instruction in chemistry and physics, be also recognised for instruction in biology; that the course of laboratory instruction in public health given at Guy's Hospital Medical School be recognised as fulfilling the conditions of the regulations for the diploma in public health; and that the Borough of Hornsey Isolation Hospital be added to the list of fever hospitals recognised for instruction in infectious diseases for the final examination of the Examining Board in England and for the diploma in public health.

Sir John Tweedy, on behalf of Mr. Sidney Young, presented to the College a transcription, made by Mr. Young, of the Book of Ordinances, dated 1435, of the Craft of Surgery of the City of London, with an illuminated frontispiece by Mr. Austin Travers Young, representing in proper colours the Arms given to the Craft by King Henry VII., in the year 1482. A report from the library committee recommending the provision of additional acommodation for the storage of books was adopted.

Government Report on Tropical Diseases.

The report of the Advisory Committee for the Tropical Diseases Research Fund for 1906 was issued last week in Blue-book form, which states that the revenue for the year amounted to £3,000, made up as follows: — Colonial Governments' contributions, £1,800; Imperial Government's contributions, £500; Indian Government's contributions, £500; Rhodes Trustees, £200.

The expenditure of the year was made up of the following grants:—£1,000 to the London School of Tropical Medicine; £500 to the Liverpool School; £750 to the University of London; and £500 to the Royal Society.

The grant to the Liverpool school was employed by the school for the payment of the salaries of a lecturer in economic entomology and parasitology, and of a lecturer in tropical medicine. The London school grant was devoted to the payment of the salaries of a combined teacher and investigator of protozoology and a combined teacher and investigator of helminthology, and to the provision of suitable apparatus. By means of the grant to the University of London there has been established a Professorship of Protozoology. The contribution to the Royal Society was employed on the research into sleeping sickness. All medical officers appointed to posts in the Crown Colonies or Protectorates are in ordinary circumstances required, before proceeding to the Colony or Protectorate, to undergo a course of three months' training at one of the Schools of Tropical Medicine. A longer period has been recommended, but the committee suggest that, if any step is taken, it should be on the lines of enabling those medical officers who are considered by the Colonial Government under which they serve to show exceptional promise, to attend a more advanced course of instruction on the first occasion of their being on leave of absence in England.

Scottish Poor Law Medical Officers' Association.

The annual report of this Association has just been issued. In it the grievances of members are referred to as having been brought before several members of Parliament, with the result that they gained the sympathies of an increased number of M.P.'s. In regard to the Royal Commissionon on Poor Law, the report states that evidence relating to Scotland is expected to be heard in June or July next, and that the chairman and secretary, along with the Scottish Committee of the British Medical Association, have had formulated a series of questions: (1) relating to the outdoor medical treatment of the sick poor; (2) relating to the indoor medical treatment of the sick poor, and (3) as affecting the general public. Joint action of the inspectors of poor, poor-law medical officers, and governors of poorhouses in Scotland had been taken on other matters which would be brought before the Commission, and they were unanimously of opinion that every poor-law medical officer should become a statutory official, only dismissable by or with the consent of the Local Government Board, as recommended by the Departmental Committee of the Local Government Board; and that Scottish poor-law officials be granted superannuation on similar lines to the Poor-Law Superannuation Act in England.

New Scholarships.

The Drapers' Company, one of the most celebrated City Guilds of London, whose generous contributions to medical institutions are so well known and appreciated by the profession, have now arranged that the munificent bequest of Mr. Thomas Appreece Soley, a past Master of the Company, shall be applied to the foundation of scholarships, each of the value of £60 per annum for two years, for the study at some place of advanced education approved by the Company, of medicine, theoretical or applied science, art, or law, or for the degree examination of some University of the United Kingdom. Boys between 16 and 18 years of age are eligible for these scholarships, which are renewable for a third year in special cases. The scheme also provides that the Company shall have the right to nominate a son or grandson between 18 and 23 years of age of a member of the Company for an exhibition of £70 per annum, tenable for three years at King's College, Cambridge. To both scholarships and exhibition a condition is attached, requiring the parent of the holder to satisfy the Company that his net income is insufficient to afford his son the educational advantages which will accrue to holders of scholarships and exhibition.

Health of the Navy.

The report on the health of the Navy for 1905 states that the returns for the force may be considered as very satisfactory. As compared with the averages of the last eight years, there are decreases in the proportions of invalidings and deaths, and this year's death ratios are the lowest recorded since 1856. The ratio of sickness per 1,000 shows a reduction of 119.29, as compared with the last eight years' ratio. The invaliding ratio, viz., 23.89 per 1,000, shows a decrease of 4.98, in comparison with the average for the last eight years. As regards the death rate the ratio per 1,000 was 3.9, showing a decrease of 1.42 when compared with the last eight years' ratio. The average number of men sick daily was 3,365.53, giving a ratio of 30.31 per 1,000, and showing a decrease of 5.44 in comparison with the last eight years' average. The total days' sickness on board ship and in hospital was 1,228,419, which represents an average loss of service from disease and injury of 11.06 days for each person, which is a decrease of 1.99 in comparison with the average of the last eight years. The total number invalided was 2,653, which is in the ratio of 23.89 per 1,000, and shows a decrease of 4.98 in comparison with the average of the last eight years. Of the above total 1,719 persons were finally invalided from the service. The total number invalided out of the Service was 1,941. Deaths numbered 433, a ratio of 3.9 per 1,000, showing a decrease of 1.42 per 1,000 as compared with the ratio for the last eight years. In the total force the average number of entries on the sick list for disease and injury per man was .73, a decrease of .02 in comparison with 1904. The average ratio of sickness per 1,000 daily was 30.31, which is a decrease of 1.04 as compared with 1904. The Channel Fleet shows the lowest sick rate. The total number of persons invalided was 2,653, of whom 2,445 were invalided for disease and 208 for injury. The death rate due to disease alone was 2.74, and that due to injuries was 1.15 per 1,000.

Society for the Relief of Widows and Orphans of Medical Men.

At the quarterly meeting of the above society held on Wednesday last, Dr. Blandford, President, in the chair, the deaths of two members were reported, and the resignation of one accepted. Three new members were elected. The deaths of two widows were also reported, one whose husband had paid a life subscription fee of £26 5s., and had received in grants £1,217, and the other £857, her husband having paid £21 in subscriptions. £536 had been distributed as an Xmas present among the annuitants of the charity. The sum of £1,275 10s. was voted for the half-yearly grants to the 48 widows and 21 orphans at present in receipt of grants. During the past quarter six letters had been received from widows of medical men asking for relief, but this had to be refused, as their husbands had not been members of the society. An application for relief was granted the widow of a member at the rate of £40 per annum. Membership of the society is open to any registered practitioner residing within a radius of 20 miles from Charing Cross. Full particulars may be obtained from the Secretary at 11, Chandos Street, Cavendish Square, W.

British Medical Association.

The preliminary arrangements for the visit of the British Medical Association to Exeter are well in hand. The meetings have been fixed for Tuesday, July 30th to Friday, August 2nd. A list of the officers of the various sections is given below. The President-Elect is Dr. Henry Davy (Exeter). The address in Medicine will be delivered by Dr. W. H. White, the address in surgery by Mr. H. T. Butlin, and the Popular Lecture by Sir J. W. Moore. The following is a list of the local medical men appointed in the several sections :—

Pathology.—Vice-President: W. L. Pethybridge, M.D., B.Sc., Plymouth; Hon. Secretary, R. V. Solly, M.D., F.R.C.S., Exeter

Medicine.—President, W. Gordon, M.D., F.R.C.P. Exeter. Vice-Presidents: W. Powell, M.B., F.R.C.S., Torquay; E. L. Fox, M.D., M.R.C.P., Plymouth; Hon. Secretary: A. B. Soltau, M.D., F.R.C.S., Plymouth.

Diseases of Children.—Vice-Presidents: L. Mackenzie, F.R.C.S., Tiverton; F. Hichens, M.D., Redruth; R. H. Lucy, F.R.C.S., Plymouth; Hon. Secretary: J. H. Gough, M.D., Torquay.

Psychological Medicine.—Vice-President: R. L. Rutherford, M.D., Exeter.

Electrical Section.—Vice-Presidents: J. D. Harris, M.D., Exeter; W. Cheyne Wilson, M.D., Plymouth.

Tropical Diseases.—Vice-President: Lieut.-Col. R. Caldwell, F.R.C.S., Plymouth; Hon. Secretary. Lieut.-Col. G. M. J. Giles, M.B., F.R.C.S., I.M.S. (retired), Plymouth

Surgery.—Vice-Presidents: E. J. Domville, M.R.C.S., Exeter; C. E. Bell, M.R.C.S., Exeter; Hon. Secretary: B. Dyball, F.R.C.S., Exeter.

Opthalmology.—President: L. H. Tosswill, M.B., Exeter; Vice-Presidents: J. R. Rolston, M.R.C.S., Plymouth; A. C. Roper, F.R.C.S.E., Exeter; Hon. Secretary: R. Pickard, M.S., F.R.C.S., Exeter.

Laryngology, Otology, and Rhinology.—Vice-President: G. Jackson, F.R.C.S., Plymouth; Hon. Secretary: C. E. Bean, F.R.C.S.E., Plymouth.

Dental Surgery.—President. J. M. Ackland, M.R.C.S., L.D.S., Exeter; Vice-President: T. A. Goard, M.R.C.S., L.R.C.P., L.D.S., Exeter.

Obstetrics and Gynæcology.—Vice-Presidents: W. F. Thompson, M.D., Launceston; W. L. Woollcombe, F.R.C.S.E., Plymouth; Hon. Secretaries: G. H. Johnson, M.R.C.S., Teignmouth; E. J. Toye, M.D., Bideford.

State Medicine.—Vice-Presidents: E. A. Brash, M.R.C.S., Exeter; F. M. Williams, M.R.C.S., Plymouth; Hon. Secretary: S. Noy Scott, M.R.C.S., Plymstock.

Naval and Military.—Vice-Presidents: Col. G. D Bourke, R.A.M.C., Devonport; Brigade-Surgeon Lieut.-Col. J. Raglan Thomas, M.D., V.D., Exeter; Hon. Secretaries: Fleet-Surgeon H. S. R. Sparrow, L.R.C.P., R.N., Royal Naval Barracks, Plymouth; Surgeon-Capt. J. R. Harper, M.R.C.S., Barnstaple; Surgeon-Capt. J. S. Steele Perkins, M.B., V.M.S., Exeter.

Local Secretaries: Russell Coombe, M.D., F.R.C.S., Exeter; G. T. Clapp, M.B., Exeter; L. R. Tosswill, M.R.C.S., L.R.C.P., Exeter. Hon. Secretary of the Pathological Museum Committee: R. V. Solly, M.D., Exeter.

Ambulance Service for Smallpox Patients.

At last Saturday's meeting of the Metropolitan Asylums Board, a letter was read from the Greenwich Board of Guardians, strongly deprecating the proposal which they said they understood had been made to discontinue the river ambulance service for small-pox patients, and to convey them by road. The letter was referred to the Ambulance Committee.

Annual Dinner of the Royal College of Surgeons, Ireland.

This annual function will take place on January 26th next. His Excellency the Lord Lieutenant has graciously signified his intention of being present. A meeting of the College will be held before the dinner for the purpose of conferring the Honorary Fellowship of the College on Mr. Priestly Smith, Professor of Ophthalmology in the University of Birmingham.

Annual Dinner of the British Gynæcological Society.

The annual dinner of this Society will be held to-morrow (Thursday), January 17th, at the Café Monico, Shaftesbury Avenue, London, W. Mr. F. Bowreman Jessett, F.R.C.S., the President, will preside, and it is hoped that there will be a large attendance of Fellows.

Amongst those who are expected to be present are the Presidents of the Royal Colleges of Physicians and Surgeons, the Master of the Apothecaries' Society, the Presidents of the Obstetrical and the Royal Medico-Chir. Societies, the Director-General of the Medical Department of the Royal Navy, and Surgeon-General Sir Thomas Gallwey, K.C.M.G. Any Fellows who have not intimated their intention of being present are requested to communicate immediately with the Secretary, Dr. Beckett-Overy, 24, Alexander Square, S.W.

NOTICES TO CORRESPONDENTS, &c.

☞ **CORRESPONDENTS** requiring a reply in this column are particularly requested to make use of a *Distinctive Signature or Initial*, and to avoid the practice of signing themselves "Reader," "Subscriber," "Old Subscriber," &c. Much confusion will be spared by attention to this rule.

REPRINTS.—Reprints of articles appearing in this journal can be had at a reduced rate, providing authors give notice to the Publisher or Printer before the type has been distributed. This should be done when returning proofs.

CONTRIBUTORS are kindly requested to send their communications, if resident in England or the Colonies, to the Editor at the London office: if resident in Ireland, to the Dublin office, in order to save time in reforwarding from office to office. When sending subscriptions, the same rule applies as to office; these should be addressed to the Publisher.

ORIGINAL ARTICLES OR LETTERS intended for publication should be written on one side of the paper only, and must be authenticated with the name and address of the writer, not necessarily for publication but as evidence of identity.

SUBSCRIPTIONS.

SUBSCRIPTIONS may commence at any date, but the two volumes each year begin on January 1st and July 1st respectively. Terms per annum, 21s.; post free at home or abroad Foreign subscriptions must be paid in advance. For India Messrs. Thacker, Spink and Co., of Calcutta, are our officially-appointed agents. Indian subscriptions are Rs.15.12.

ESTER.—The relationship between University College and University College Hospital has been a very close one in the past, the hospital having been governed by the Council of the College, though actually managed by a committee. Lately this relation has been changed entirely. The Hospital is now to be a separate corporation. The hospital funds and school funds are to be entirely distinct.

CANIS SUM.—The name of the energetic member of the "nine miles long" petition is Mr. Ellis Griffith. He is the Liberal Member of Anglesey. There was 400.000 signatures; we do not know why they could not have been condensed into a smaller space, but the advertisement of the cause would have been less.

A CURE FOR INSOMNIA.

THE Vicar of Burgess Hill Parish Church is currently reported to have told his parishioners that many cures for insomnia were advertised, but medical men never recommended the most certain cure—a sermon! If anyone troubled with insomnia would only go to his church and listen to his sermon, he could promise the patient the most cosy of naps.

INQUEST.—The diagnosis would seem to lie between ringworm of the nail and chancre of the finger. Microscopical examination would easily demonstrate the former, but the search for Schaduin's spirochœte would be a longer, more tedious, and less certain business.

A. S. R.—The patient might be fairly regarded as yours under the circumstances. The question is whether he is worth having in any case.

DR. ADOLF ERDOS.—The Medical Sickness and Accident Society insures its members against accident and sickness in Great Britain, but we have no information whether these privileges are extended to practitioners resident abroad. You will see a reference to this Society in our last issue, page 51.

Meetings of the Societies, Lectures, &c.

WEDNESDAY, JANUARY 16th.

ROYAL MICROSCOPICAL SOCIETY (20 Hanover Square, W.).—8 p.m.: Exhibition of Mounted Specimens by Mr. Rousselet. Annual Address:—The President: The Flowering Plants of the Mesozoic Age in the Light of Recent Discoveries.

MEDICAL GRADUATES' COLLEGE AND POLYCLINIC (22 Chenies Street, W.C.).—4 p.m.: Mr. J. Berry: Clinique. (Surgical). 5.15 p.m.: Lecture:—Dr. E. Cautley: Asthma in Infancy and Childhood.

CENTRAL LONDON THROAT AND EAR HOSPITAL (Gray's Inn Road, W.C.).—5 p.m.: Demonstration:—Mr. C. Nourse: Larynx.

NORTH-EAST LONDON POST-GRADUATE COLLEGE (Tottenham Hospital, N.).—2.30 p.m.: Cliniques:—Dermatological (Dr. Meachen), Ophthalmological (Mr. Brooks), Medical (Mr. Whipham).

THURSDAY, JANUARY 17th.

MEDICAL GRADUATES' COLLEGE AND POLYCLINIC (22 Chenies Street, W.C.).—4 p.m.: Mr. Hutchinson: Clinique. (Surgical). 5.15 p.m.: Lecture:—Mr. R. Jones (Liverpool): On the Treatment of some Paralytic Deformities.

NORTH-EAST LONDON POST-GRADUATE COLLEGE (Tottenham Hospital, N.).—2.30 p.m.: Cliniques:—Gynæcological Operations (Dr. Giles), Medical (Dr. Whiting), Surgical Out-patient (Mr. Carson). 4.30 p.m.: Lecture:—Mr. Edmunds: Diseases of the Thyroid Gland.

ST. JOHN'S HOSPITAL FOR DISEASES OF THE SKIN (Leicester Square, W.C.).—6 p.m.: Chesterfield Lecture:—Dr. M. Dockrell: Syphilis: I., History and Primary Invasion (Constitutional and Local). Erythematous: I., Macular; and II., Maculo-Papular.

FRIDAY, JANUARY 18th.

SOCIETY FOR THE STUDY OF DISEASE IN CHILDREN (11 Chandos Street, Cavendish Square, W.).—5 p.m.: Cases will be shown by Dr. F. J. Poynton, Mr. H. S. Clogg, Dr. E. Cautley, Mr. P. L. Mummery, Dr. C. O. Hawthorne, Dr. T. R. Whipham, Dr. G. Carpenter, and others.

EPIDEMIOLOGICAL SOCIETY (11 Chandos Street, Cavendish Square, W.).—8.30 p.m.: Microscopical Demonstration:—Dr. J. B. Murray. Paper:—Dr. E. F. Bashford: Real and Apparent Differences in the Incidence of Cancer.

MEDICAL GRADUATES' COLLEGE AND POLYCLINIC (22 Chenies Street, W.C.).—4 p.m.: Dr. StClair Thomson, Clinique. (Throat.)

POST-GRADUATE COLLEGE (West London Hospital, Hammersmith Road, W.). 10 a.m.: Dr. Moullin; Gynæcological Operations. 2 p.m.: Medical and Surgical Clinics. Dr. Ball: Diseases of the Throat, Nose, and Ear. 2.30 p.m.: X-Rays. Operations. Dr. Abraham Diseases of the Skin. 5 p.m.: Clinical Lecture:—Mr. Armour.

NORTH-EAST LONDON POST-GRADUATE COLLEGE (Tottenham Hospital, N.).—9.30 a.m.: Clinique. Surgical (Mr. H. Evans). 2.30 p.m.: Surgical Operation (Mr. Edmunds). Clinique. Medical Out-patient (Dr. Auld), Ophthalmological (Mr. Brooks). 3 p.m. Clinique. Medical In-patient (Dr. Leslie).

SATURDAY, JANUARY 19th.

LONDON SCHOOL OF CLINICAL MEDICINE (Dreadnought Hospital, Greenwich).—2.30 p.m.: Operations. Out-patient Demonstrations. 10 a.m.: Surgical and Medical. 11 a.m.: Eye.

Vacancies.

Carmarthen, Cardigan, and Pembroke Joint Counties Lunatic Asylum. Carmarthen—Junior Assistant Medical Officer. Salary £150 per annum, with furnished rooms, board, washing, and attendance. Applications to W. Morgan Griffiths, Clerk to the Asylum Visitors, Carmarthen.

Edinburgh School Board.—Medical Officer. Salary £400 per annum. Applications to G. W. Alexander, Clerk, School Board Offices, Edinburgh.

Liverpool Dispensaries.—Head Surgeon. Salary £200 per annum, with board and apartments. Applications to K. Stretch, Auditor. 56 Vauxhall-road, Liverpool.

Liverpool Dispensaries.—Assistant Surgeon. Salary £100 per annum, with board and apartments. Applications to K. Stretch, Auditor, 56 Vauxhall Road, Liverpool.

Bath Royal United Hospital.—Resident Medical Officer. Salary £100 per annum, with board, lodging, and washing. Applications to J. M. Sheppard, F.C.I.S., Secretary

Royal Cornwall Infirmary, Truro.—House Surgeon. Salary £100 a year, with board and apartments. Applications to J. C. R. Crewes, 4 Parkvedras-terrace, Truro.

Rochdale Infirmary.—House Surgeon. Salary £100 per annum, with board, residence, and laundry. Applications to Henry Booth, Secretary, Infirmary Offices, 38A, Yorkshire Street, Rochdale.

Newport Borough Asylum, Caerleon, Mon.—Assistant Medical Officer. Salary £125 per annum, with board, apartments, and attendance. Applications to the Medical Superintendent.

Cameron Hospital, West Hartlepool.—House Surgeon. Salary £100 per annum, with board, rooms, and washing. Applications to J. G. Taylor, Secretary.

Sir Patrick Dun's Hospital. Assistant Surgeon. Immediate application to Secretary, Medical Board. (See advt.).

Appointments.

COGHLAN, E. F., M.R.C.S., L.R.C.P.,Edin., Clinical Assistant to the Chelsea Hospital for Women.

GUBB, ALFRED, S., M.D., M.R.C.S., Honorary Physician to the British Consulate at Mustapha Supérieur, Algiers.

LAMBKIN, F. J., Brevet-Colonel, R.A.M.C., Lecturer in Syphilology at the Royal Army Medical College.

LATHAM, ARTHUR M.D., B.Ch.Cantab., F.R.C.P.Lond., Advisory Physician to the Hospital for Diseases of the Throat, Golden Square.

LAWRENCE, ARTHUR GARNONS, M.D.St.And., M.R.C.S., L.S.A., J.P., Medical Officer of Health for Chepstow.

MARTIN, JAMES PIRIE, L.R.C.P.Lond., M.R.C.S., Medical Officer for the Districts of Box and Colerne by the Chippenham (Wilts) Board of Guardians.

MIDDLETON, E. W, M.D.Balt., Clinical Assistant to the Chelsea Hospital for Women.

OSMOND, CHARLES HOLDWAY, L.F.P.S.Glas., L.S.A., District Medical Officer by the Bristol Board of Guardians.

PATRICK, J. KING, M.B., Ch.B.Glasg., Anæsthetist to the Glasgow Royal Infirmary.

PRINGLE, A. M. N., M.B., C.M.Edin., Certifying Surgeon under the Factory and Workshop Act for the Ipswich District of the county of Suffolk.

SHORNEY, H. F., M.D., B.S.Melb., Resident Medical Officer to the Hospital for Diseases of the Throat, Golden Square, W.

Birth.

HARTLEY.—On Jan. 7th, at 4, De Parys Avenue, Bedford, the wife of Arthur Conning Hartley, M.D., F.R.C.S.Edin., of a daughter.

Marriages.

GARLAND—AVELING.—On Jan. 9th, at St. Matthew's Church, Upper Clapton, Frank Hooper, fourth son of Thomas Garland, of "Trenance," Stamford Hill, to Dorothy Mary, youngest daughter of the late C. T. Aveling, M.D. of Stamford Hill, and Mrs. Aveling, of 88 The Common, Upper Clapton.

PRANCE—BULLOCK.—On Jan. 10th, at St. John's Church, Putney, George Frederick Charles, youngest son of the late Robert Rooke Prance, M.D., of Hampstead, and Mrs. Prance, 35 Netherhall Gardens, Hampstead, to Frances Beatrice, youngest daughter of the late Henry Bullock, F.R.C.S., of Spring Grove, Isleworth.

Deaths.

BLAKE.—On Jan. 9th, at Jubbulpur, India, William Twynam Blake, B.A.Cantab., Indian Civil Service, the eldest son of William H. Blake, M.B., B.S., of Harpenden.

GROTH.—On Jan. 6th, at 22 Panton Street, Haymarket, London, Ernest Groth, M.D., Physician to the German Hospital, and formerly Physician Deaconesses' Hospital, Tottenham, and Senior Physician Islington Dispensary, in his 67th year.

EVANS.—On Jan. 13th, at 89 Savernake Road, Parliament Hill, London, T. C. Evans, M.R.C.S.Eng., and L.S.A Lond., late Surgeon Superintendent, Indian Emigration Service, aged 51.

THE MEDICAL PRESS AND CIRCULAR.

NOTES AND COMMENTS.

Zancigomania. THE question of the hour that is agitating those large sections of society where science is taboo and thought a bore, is whether the Danish music-hall performers calling themselves the Zancigs are or are not telepathists (whatever that may mean). The lady and gentleman in question, by a judicious method of advertisement and by a still more judicious invitation to appear before the King, have succeeded in focussing a prodigious amount of popular attention on their tricks. The lady Zancig, wearing spectacles, stands on the stage at the Alhambra, while her husband in the auditorium puts to her conundrums suggested by people around. The lady, with great facility, grasps what is intended, and gives the answer in a commendably brief period. Now were we not too old to be surprised at anything, we should wonder why this performance should be leading to domestic crises as acute as those of the Tichborne times; indeed, the display of the Zancigs seems to us considerably less astonishing than finding a pack of cards in the leg of a pair of dress-trousers or extracting a white rabbit (which is not there) out of a top-hat. The difference between scientific men and the laity is that whereas the former, in contemplating a phenomenon, *a priori* assume a natural explanation, the latter prefer for romantic reasons to assume an *a priori* metaphysical one. In other words, scientific men want to know the truth, and unscientific people prefer not to know it. As for the present Zancigomania, one can only congratulate the Danes—who must be the reverse of melancholy—on their astuteness, and the British public on their incurable stupidity.

Magic Boots. THE American criminal lawyer is a species all his own, for nimble-witted as are many of our own advocates, it must in fairness be conceded that they cannot hold a candle to their Transatlantic brethren for unscrupulous ingenuity. A remarkable person has just been tried in the Supreme Court in New York for an offence we have not yet encountered in this prosaic land, to wit, selling magic boots. This latter-day Jack-the-Giant-Killer was a cobbler by trade, and finding soleing and heeling but a slow path to affluence, he conceived the idea of endowing his creations with magical powers. Electricity was the instrument selected for this purpose, and he put forward magnetised boots warranted to cure a number of diseases of which rheumatism and locomotor ataxy were two of the least conspicuous. The boots sold like hot cakes, £20 being by no means an out-of-the-way sum for a pair. Eventually the American law took their creator into its meshes on a charge of violating the Medical Act. The defence made by his lawyer was worthy of a better cause. The magic was dropped, and counsel set forth that Hilgert, his client, was an experienced and scientific boot-maker. Now poor health is due to an unbalanced state of the human system, and by scientific boot-making the balance could be restored. Hilgert's "scientifically-made boots not only assist locomotion, but also assist the circulation of the blood, which is life." But in spite of his advocate, the defendant apparently could not resist the temptation of claiming magic for his goods, for in the box he explained that by wearing these boots his clients, one of whom was Dr. Potter, Bishop of New York, found it unnecessary to wear braces! The only explanation of this remarkable phenomenon which occurs to us is that braces are clearly unnecessary in the presence of straight-jackets

£50 a Pig. THE consideration of this point leads us to wonder whether now that mechanical restraint is all-but removed from our asylums, it might not be possible to put a little more moral restraint on some of their administrators. Mr. Davey, Chief Inspector of the Local Government Board, is not likely to speak except by the card, and in his evidence before the Royal Commission on the Care of the Feeble-Minded last week he mentioned some facts about lunatic asylums which would really seem to be more appropriately connected with the inmates than with their governors. Let us not be understood to wish for anything but the most considerate and humane treatment for the insane, and we certainly do not agree with Mr. Davey when he said that he could not understand why entertainments and tennis-courts should be provided in asylums. Such measures are necessary parts of curative treatment. But it is hardly credible that an asylum architect should be so modest as to wish to provide separate mortuaries for male and female patients! "Corruption," said Mr. Davey very truly, "hangs round the skirts of extravagance," and he instanced as an example of the latter a proposal in Sussex to build pig-styes which worked out at £50 a pig! Without commending the average stye, we cannot help supposing there is some happy sanitary mean between it and the luxurious cottage which that sum would connote.

An "O" Too Much.

ON Dr. Doyen, his micrococcus, his serum, and his biograph, we have had frequent occasion to comment in these columns. We have also touched lightly upon the question of his fees, but have not enjoyed full opportunity of forming a judgment. From news that comes from Paris, his charges seem to be modelled on the same Napoleonic lines as the other attributes of that extraordinary person. In the present case, Mr. Crocker, a wealthy American whose wife was suffering from malignant disease, heard, doubtless through the agency of his native press, of Dr. Doyen's wonderful new cancer serum, and the poor patient was hurried over to France to be cured by it. The extent of Dr. Doyen's ministration, according to Mr. Crocker, consisted in paying six visits, administering eleven injections, and writing eight prescriptions. Mrs. Crocker grew obviously worse, and was taken home just in time to die. On the subject of fees, Dr. Doyen's modesty at the beginning of the treatment—he referred Mr. Crocker to his "business manager," as he himself could not discuss such mundane affairs—was only equalled by the business manager's effrontery when Mrs. Crocker was well under treatment, for he sent to her husband to inform him that the fees were £4,000, and payment in advance was expected. One cannot be surprised at Mr. Crocker writing to ask if there were not an "o" too much. Indeed, as fees rule in this benighted country and in America, even specialists are expected to do a precious deal for £400. However, the secretary politely replied that there was no error, and the money was subsequently paid. Were £650 a visit at all a common rate of remuneration, we can imagine that even peers might find medicine a more pleasing calling than promoting and directing bogus companies in the City.

Undertaking—A Conscientious Objection.

THE now famous Mrs. Green explained to her neighbour that there were "'usbands and 'usbands"; "ours," she added pathetically, "are the and 'usbands." There would seem on that analogy to be conscientious objectors and conscientious objectors, and an amusing variety of the latter class was recently furnished at the Southend Police Court, where an applicant who was asked his reason for claiming exemption said that he was an undertaker! The Bench apparently did not see that this cheerful calling coincided with the loop-hole provided by the Act, and the plea was held not to be valid. True, the undertaker has since written to the press to explain that in the pursuit of his calling he has been employed by mothers who had attributed their children's death to vaccination, but in such cases the "funeral furnisher" would do better to consult the death certificates in the possession of the registrar than take unconfirmed the expert opinion of uneducated mothers. One would have thought surely the last man to object to a rise in the death rate would be the undertaker.

LEADING ARTICLE.

PROPOSED CHARTER OF THE KING EDWARD VII. HOSPITAL FUND.

THE relationship of the various hospital funds to the community at large is obviously a matter of considerable public interest. These funds distribute vast sums of money for the benefit of the medical charities in various parts of the United Kingdom. In addition to the functions of collection and distribution, the funds have latterly exercised a sort of disciplinary control over the management and the policy of the hospitals to which they make grants of money. Properly exercised, this power is doubtless capable of much salutary effect upon hospital executives, but it must be borne in mind that the decision of the funds is absolute and irresponsible. No matter how harsh and arbitrary their action may appear, they are not called upon to state their reasons for adopting any given course. As a case in point their action regarding the Royal Orthopædic Hospital may be quoted. This institution stood upon an enormously valuable freehold site in Oxford Street. It was proposed to sell the ground, and in spite of the resolute opposition of a minority of governors, that course was ultimately adopted, under the chairmanship of Mr. Harry Marks, M.P. The Hospital Sunday and King Edward's Funds pressed on the transaction by urging amalgamation and withholding grants. To-day the site is covered with most valuable buildings; the birthright of the Royal Orthopædic is gone, and its financial resources merged inextricably in those of the amalgamated institution. The Funds were kept informed of what was going on by the *Lancet* and by THE MEDICAL PRESS AND CIRCULAR. Especially were they apprized of the fact that the opposition had forced up the sale price of the hospital by no less than £12,000. At the time we challenged the Funds to institute a public enquiry into the affair. We now ask whether they dare bring out their records of information and minutes of investigation before they undertook the serious responsibility of urging the sale of the hospital site. We have treated this matter at some length because it so forcibly illustrates the powers of the Funds, as well as the absolutely irresponsible way in which they may be exercised. At the present moment the reminiscence has no little point. The youngest, but not the least wealthy, of the Metropolitan funds is that founded by King Edward. It has leapt into popularity almost at a bound, and its coffers are replenished in a way that emphasises not only the wealth, but also the divine gift of charity that is possessed by our fellow-countrymen. Nevertheless, we believe that the King Edward's Fund is constituted on a basis that is unsound, and that must be rectified if the Fund is to survive as a permanent institution. The inherent flaw is its non-representative character—the absence of representation of the medical charities, which are true beneficiaries of the funds, and of the medical profession, by whose gratuitous services those charities are conducted. In fact, the management of the King Edward's Fund is as autocratic and irresponsible as any secret Russian bureau. It is no answer to say that the *personnel* and the motives of the Fund are above suspicion. We have given one instance in which we believe the Fund's judgment was defective, its action arbitrary, its information possibly or probably imperfect, and its guidance unduly biassed. We are prepared to furnish further instances of *prima facie* injustice in the dispensation of grants. Apart from particular instances, the general viciousness of autocratic control in a great public institution, supported by public money and devoted to public benefit, is to our mind sufficiently apparent to condemn the whole thing. Holding these views, it was with nothing less than a shock of pained amazement that we read the Bill to incorporate the King Edward's Fund. This short Bill was recently published by the *British Medical Journal*, and we reproduce it in another part of our present issue for the benefit of our own readers. Briefly put, the Bill provides for the autocratic government of the Fund by placing full and supreme powers in the hands of the President. The principle thus adopted is reactionary and absolutely out of touch with the spirit of the age. The present President is the Prince of Wales, who has on various occasions shown himself possessed of a strong will and a sound judgment. In this instance he will do well to think twice before giving his sanction to a method of control that has always been repugnant to Englishmen. At this very moment the medical profession is in revolt against the hospital system, and as they provide the honorary staffs of the medical charities, and their professional interests are seriously affected by hospital competition, surely they are entitled to representation on the Council of the King Edward's Fund. Every hospital, large and small, within the Metropolitan area has a clear right to representation. As things go some of the professional philanthropists and *ex officio* members of the Fund Council are committed to a policy of exterminating the small hospitals and of exacting payment from hospital patients. Why should not the general practitioner, the small hospitals, and the poor patients themselves all have a vote in the management of King Edward's Fund? The voice of the people must sooner or later assert itself in this as in all other public questions with which they are intimately concerned. It is impossible to think that our great King, who has always shown himself in sympathy with the wise independence of his subjects, will allow the Fund he has created to become a potential instrument of injustice and abuse by reason of the absence of popular representative control. Nor can we imagine the Prince of Wales for a single moment giving his approval to any scheme of the kind—that is to say, when the consequences have been duly set forth. In conclusion, we may add that this protest has been entered as a simple act of duty, and it in no sense detracts from our grateful admiration of the kindness, the graciousness, and the sustained sympathy with which this particular institution has been founded, fostered, and brought to maturity by His Majesty King Edward.

CURRENT TOPICS.

The Edalji Case.

THE efforts of Sir A. Conan Doyle have not so far prevailed upon the Home Office to grant a "free pardon" for the offence which it now seems to be generally as well as officially admitted was never committed by Mr. Edalji. However, the time is still young, and the *Daily Telegraph* may yet vindicate the right of the people of this country to review the administration of criminal law. Clearly, an immense volume of public feeling is concentrated upon the case. A flood of correspondence, containing a host of suggestions and criticisms, has been poured into the columns of the *Telegraph*. But it has remained for a correspondent of our own to advance the theory that the crime was purely artificial, that is to say, manufactured deliberately for the sake of obtaining incriminating evidence. Such a possibility is, of course, too far-fetched to be considered seriously. On the other hand, imagination fails to grasp the set of circumstances under which it was possible for any human being to steal into a field at night and commit a crime of so gross and violent a nature when the field itself, not to mention its approaches, was closely guarded by a vigilant body of police constables. Some human hand must have committed the outrage. The police assert that Mr. Edalji was the criminal, and at the trial they supported the case by a mass of untrustworthy circumstantial evidence. That being dismissed as untrue, are the county police now absolutely at fault as to the alternative culprit? So far as Sir Conan Doyle's theory of Edalji's inability to find his way about at night by reason of defective sight, we express no definite opinion, but regard the burden of proof as still resting upon its author. A week ago that distinguished writer appealed to the three leading journals for an answer to the particular point. In return we furnished the view of a medical authority in questions of vision. It is a matter of some personal congratulation to ourselves that the MEDICAL PRESS AND CIRCULAR alone among the medical journals spoke out decisively against the justice of Edalji's conviction so long ago as the year 1903. The case demonstrates the necessity of a Court of Criminal Appeal, if we would avoid similar miscarriages of justice in the future.

The Fallacy of Big Muscles.

It is high time the medical profession spoke out upon the modern craze for physical development. The confusion that has not unnaturally arisen in the mind of the populace is to mistake big muscles for a strong constitution. As a matter of medical observation it is often exactly the other way about. The great athlete with the build of a prizefighter and the muscular strength of a gladiator throws up the sponge and dies forthwith when attacked with influenza or some other malady that would be readily surmounted with ordinary precautions by the plain man of average stamina. More than that, the heart is often damaged in the strain of developing big muscles, and it seems pretty certain that the body resistance of the muscular giant to disease is less than that of the man in the street who is content to have at command a moderate amount of strength sufficient to meet the everyday exigencies of life. The sooner the "strong man" error is scotched publicly the better, and Staff-Surgeon A. Gaskell, who recently discussed the subject, in an official report, may be congratulated on the bold way in which he has attacked what a journalist has picturesquely called the "cult of the bulging biceps." Most medical men of experience know the pale, attenuated, ailing patient who pulls through all kinds of untoward symptoms, but who nevertheless outlives scores of friends and relatives of boisterous health and strength.

The Fasting Man in "Fun City."

The ghastly exhibition of Sacco, the fasting man, in the so-called "Fun City" in the London Olympia, offers one of those sharp contrasts not unfamiliar in modern life. On the one hand we see crowds of pleasure-seekers, while on the other we have a poor wretch trying to beat his previous record of endurance against starvation. One newspaper account states in so many words that Sacco is already a dying man. He has undertaken a fast of fifty days, allowing himself only cigarettes and mineral waters, and on the twenty-seventh day he has lost no less than thirty-four pounds weight. The reporter described him as terribly wasted and scarcely able to stand up. We have often in the columns of THE MEDICAL PRESS AND CIRCULAR protested against the gross folly and inhumanity of such exhibitions. The limit of human endurance has long since been ascertained for all practical purposes, and the death of Sacco is not needed to fix a fatal point, which after all can only be absolutely true for his individual case. We are strongly of opinion that all public performances or shows involving probable danger to human beings should be rendered illegal by the legislature. If Sacco dies at Olympia, an event that seems to be well within the bounds of probability, the police would do well to enquire if there be not some legal method of prosecuting the authorities of "Fun City" for their share in the matter.

The Unqualified Practitioner of Medicine.

EARLY in the present month the Liverpool coroner was called upon to investigate a case in which a child died after being seen and prescribed for by an unqualified American, named M'Kay. It appears that the same man has been previously warned as to his conduct by the City Coroner. On this occasion the mother of the child said that the name of "Dr. Ross" was on a lamp outside the surgery, and she went there expecting to see some one of that name. The man M'Kay appears to have assumed a tone of effrontery, if not of defiance. He asserted that the name of Dr. Ross was painted over, and that half-a-dozen tenants had been there since Dr. Ross. In seeing the child he asserted he was doing nothing wrong, and that it was not nice "to be dragged to that Court for the sake of a sixpenny bottle of medicine." His own name was on the door in big letters. Surely on the facts as reported, M'Kay could be prosecuted by the police, not only for an offence under the Apothecaries Act, but for personation and obtaining money under false pretences. If the local medical men have no machinery capable of setting the law in action, one of the medical defence unions would probably take up the case. The duty should clearly fall to the General Medical Council, were it representative of the medical profession, instead of being an autocratic and irresponsible administrative body.

The Insurance of Servants.

MEDICAL men, like the rest of the community, will have to bestir themselves in the face of the fresh Workmen's Compensation Act, which comes into operation in July next. The new feature that is likely to affect medical men as employers is the inclusion of domestic servants within the range of compensation for accident or sickness contracted in the course of their employment. Should a servant slip down and break her fibula, or develop housemaid's knee from kneeling, or be laid up from a great variety of other causes, the employer will, after next June, be called upon to compensate him or her upon a fixed scale. In the existing depressed state of medical incomes, at any rate among the rank and file of the profession, it would be impossible to incur such a potential addition to possible expenses. A run of trivial domestic accidents and sickness might readily prove the last straw upon the camel's back, when the margin is already cut down to its narrowest possible proportions. All medical men will therefore have to insure their employees, and we shall hope before long to have in our advertising columns particulars of some solid and substantial company prepared to undertake this class of business.

Health of London and Dublin Compared.

THE Public Health Committee of the London County Council have reason to be proud of the fact that since 1891, the date of the Public Health

(London) Act, the death-rate has fallen by some 30 per cent., from 21 per thousand to 15.1 per thousand. It is also gratifying that the rate for 1905 is the lowest on record. No better illustration of the value of wise sanitary administration could be offered. What has been done in a huge and dense population such as that of London ought surely to be attainable in lesser cities. Nevertheless, the death-rate in many cities with a population under half-a-million is still alarmingly high. In Dublin, during the past few months, the annual death-rate, as calculated from weekly records, has, on more than one occasion, been above 30—twice the average rate in London. It has constantly fluctuated about 25. Dublin is a city with many advantages from the point of view of sanitary administration. It has an excellent water-supply, many open spaces, and from its position is easily drained. Nevertheless, it contests with Moscow and Trieste for the highest death-rate in Europe. People are wonderfully tolerant of anything to which long use has accustomed them, but it is surely time that some attempt were made to explain the extraordinary mortality to which Dublin is subject, and to deal with the health problem in a radical fashion.

Railway Carriages and Disease.

WE have often drawn attention to the part played by insanitary railway carriages in the dissemination of disease, and it is certainly true that during the past few years there has been evident some slight endeavour on the part of the companies to suit themselves to modern requirements in regard to cleanliness. There is still, however, much to be done in that direction. It is true that notices appear here and there prohibiting promiscuous spitting, but on many lines they are still absent, and on others they are regarded both by passengers and officials as a dead letter. We have, indeed, heard a distinguished lawyer, now holding a judicial position, maintain that "no law could prevent a man spitting where he chose." The law can do it, however, but it is not often put into operation. Moreover, on many lines there is little attempt to keep the floors of the carriages in a cleanly condition, and ventilation is usually deficient, as the ordinary passenger has a dread of open windows. As far as Ireland is concerned, there appears to be at present an excellent opportunity of urging sanitary reform on the carrying companies, since there is sitting a Vice-Regal Commission to inquire into the management of the Irish railways. It is to be hoped that some representative body interested in the health of the country may bestir itself to offer evidence on the subject.

PERSONAL.

THE DUCHESS OF ALBANY has consented to become patron of the Infants' Hospital which is being built in Westminster.

DR. DAVIDSON is one of the candidates who will contest Hammersmith in the Labour interest.

DR. EDWARD CARNELL, of Harrogate, has been made a member of the Livery of the Apothecaries' Society.

MAJOR R. W. H. JACKSON, R.A.M.C., has been appointed Specialist Sanitary Officer for the Belfast District.

DR. MAYNIER and DR. ROBERTSON and his wife are reported to be among those killed in the earthquake at Kingston.

DR. SAVAGE, of Birmingham, with his nephew and niece, who were in Jamaica, are missing.

MAJORS HUTTON and MARGIN, R.A.M.C., and Lieut. SIDGWICK, R.A.M.C., were injured in the same catastrophe; the last-named gentleman sustained a compound fracture of the leg, but is reported to be progressing favourably.

MR. E. M. WRENCH, F.R.C.S., of Bakewell, Derbyshire, has been decorated with the fourth class of the Royal Victorian Order.

SIR WILLIAM CHURCH, K.C.B., took the chair at the annual dinner of the University College Colston Society at Bristol.

BARON KOMURA, the Japanese Ambassador, has promised to be present at the dinner of the new University of Leeds on January 31.

LIEUT.-COLONEL GUY CARLETON JONES has been gazetted Director-General of the Army Medical Services of Canada, *vice* Colonel Fiset, D.S.O.

DR. SINCLAIR BLACK, of the Robben Island Leper Hospital, will read a paper on Leprosy in South Africa at the Polyclinic on Friday next.

A COMPLIMENTARY dinner was given to Dr. Bruce, of Dingwall, on his retirement from the General Medical Council. Sir William Turner, K.C.B., was in the chair.

DRS. DAVIES (Hoxton), Baxter Forman (South Kensington), W. R. Smith (St. George's-in-the-East), and Vosper (West St. Pancras) are standing as Moderate candidates.

SIR JAMES BARR will take the chair at the dinner of the hospitals amalgamated with University of Liverpool to-night. Lord Derby and Sir John Moore are to be present.

MAJOR-GENERAL LORD CHEYLESMORE will give away the prizes to the London Companies of the R.A.M.C. Volunteers at their headquarters, Calthorpe Street, W.C., on February 9th.

THE names of Drs. Salter (Bermondsey), Searson (West Marylebone), and Dr. Beaton (North St. Pancras, are announced as Progressive candidates for the forthcoming election of the London County Council.

MISS ANNIE W. HYATT, M.B., has been elected deputy to her father, Dr. J. T. Hyatt, Medical Officer of Health for Shepton Mallett U.D.C. Confirmation of the appointment will be needed from the Local Government Board.

SIR CHARLES CAMERON, M.D., F.R.C.S.I., C.B., has been appointed a member of the Advisory Board for the Army Medical Service as representing Irish Sanitation.

MR. W. DUNNETT SPANTON, F.R.C.S., J.P., consulting surgeon to the North Staffordshire Infirmary, has been elected President of the British Gynæcological Society for the current year.

A CLINICAL LECTURE ON THE MENTAL RISKS OF ADOLESCENCE.

By T. S. CLOUSTON, M.D., F.R.C.P.,

Physician Superintendent, Royal Asylum, Edinburgh; Lecturer on Mental Diseases, University of Edinburgh.

The meaning of the word "adolescence" is not always definitely understood. It is often used synonymously with the word "puberty," but this is undoubtedly a mistake. Puberty denotes the onset of the reproductive function. Adolescence means its slow and gradual development, co-ordinately with development of the whole organism, until full manhood or womanhood is attained. We shall be near the mark if we count adolescence as on the average covering the years from fifteen to five-and-twenty. It is the period of life which, until lately, had not attracted the attention it deserved either from the biologist, the physiologist, or the pathologist. Professor Stanley Hall has lately written two exhaustive volumes on every aspect of adolescence which, if they err in any way, do so by over-fulness of treatment. To-day we have to look at adolescence from the clinical point of view, and we shall confine ourselves chiefly to the mental aspect of the clinical disturbances. It would be unscientific, however, to exclude the consideration of the motor, sensory and nutritional risks of adolescence. As a matter of fact, that cannot be done. Few of the mental disturbances to which adolescence is liable but are accompanied by either motor, sensory or nutritional disturbances. The physiological and the psychological issues of adolescence are the most momentous of any period of life. Intelligence, emotion, volition, character, inhibition, and every feeling relating to sex are involved in it. It is the period when there is a continuous adaptation going on in a hundred ways between the most delicate organic structure in Nature and its functions and the environment of a highly complicated and specialised life—that of modern society. This process of adaptation depends for its success on a healthy machinery in the mental cortex of the brain. The health of that marvellous organic structure means that it has the power of continuous development on certain normal lines, that its resistiveness to outward and inward causes of functional disturbance shall be great, and that its reactiveness to its environment, mental and bodily, shall go on without explosiveness or mental failure. I shall only say here that the adolescent period is subject to almost every form of neurosis as well as the mental, and that they all, when occurring at this period, are tinctured by the developmental or adolescent character.

I shall divide the clinical examples of adolescent mental risks into three sections. The first will represent the risks which I was going to call minor, but by that term I do not mean that they are of small importance. I include in it the examples of mental unfitness for work, of mental "breakdown," of unfitness for school life, and of a certain mild paralysis of mental action, all of which are by no means uncommon. I also include in it the cases of simple diminution of volitional power, so that irresolution, fickleness, want of power to follow any kind of continuous work, morbid laziness, and lack of mental energy are the chief characteristics. I also include cases illustrating a paralysis or perversion of the social instincts, so that affection for father, mother, brothers and sisters is no longer exhibited. This is very frequently so accentuated that there is a positive aversion to those nearest to the patient. I include cases where the temper becomes so bad that almost all inhibition over it is lost; cases of such a mild emotional depression that the patients cannot enjoy life in a normal way are also placed in this section. Along with those I put the cases where common sense is lost, and there is exhibited a visionary optimism which passes all reasonable bounds, where, in fact, there is a mild cortical excitement. I shall also include the cases where there is a frothy religionism exhibited that has no relation to duty. I also include the case that breaks out into spasms of immorality of every kind, especially sexual immorality. All those cases exhibit mental risks that mostly cannot be called insanity in the technical sense, although they are first cousins to that condition. None of them can be properly understood except by taking physiological and medical views of the symptoms. The ordinary ethical and educational views of such cases, without regard to the faults of brain working, are necessarily incomplete, and are mostly wrong. They are not only wrong in their diagnosis, but they are wrong also in their modes of treatment of those conditions.

The first case illustrating my thesis is that of a delicate-looking girl of 16, with all the appearances of a neurotic constitution. She had been a nervous child, but it was only after she went to school that anything very marked was noticed in her mental constitution. Before puberty she learned her lessons fairly well, but with occasional difficulties in applying her mind to them. Lately, she has exhibited the following very striking condition:—When spoken to she talks rationally on any subject. In conduct and appearance there is little difference between her and other girls of her age. Her memory is good, her intelligence is in many ways above the average, but she is extraordinarily super-sensitive in regard to her school work. She is intensely desirous to do it well, but has become utterly and absolutely unfit within the past few months to do any kind of lessons, to do any reading even, or systematically to apply her mind in any direction whatever, even to simple knitting or ladies' work. There is a slight tinge of depression in her emotional nature, she has not the elasticity and spirits of the average girl of her age. She has got somewhat thinner lately, and her sleep is not altogether satisfactory. She is perfectly conscious of those mental deficiencies, and it worries her. Herditarily she came of a very nervous stock on her father's side. She had at least two paternal uncles insane. She was gentle, and seemed to have no bad habits whatever. There could be no doubt that this whole condition was the result of disease and not of moral obliquity or an unwillingness to do her school work. I, of course, stopped all lessons or any reference to lessons, and literally "turned her out to grass," to live in the fresh air, to have plenty of milk and fattening diet, to have some Maltine and Parrish's syrup, and I told her mother that for two years school or lessons were not to be mentioned to her—that her employments were to be entirely hand and not head occupations. During those two years she lost all these peculiarities, and after some months got much stouter. She still remains somewhat nervous, but I think has a reasonable chance of getting through life without any attack of acute insanity or passing into dementia, of which I think she ran great risk had her school education been persisted in. Such a girl should certainly never marry if the good of future generations is considered.

The second example of those minor risks was that of a girl who, up to 15, had been somewhat like ordinary children, but from that time on to 20, when I saw her, she had developed the most extraordinary series of moral and social perversions that it was possible to conceive. She was not stupid, and she was not immoral in the sexual sense, but she took a violent dislike to every near relation she had, especially to her mother—a gentle and too indulgent parent—and her conduct generally at home became simply abominable. She was disobedient, rude, untruthful, with no sense of right and wrong, and with nothing that could rightly be called a concience. Her whole social nature was perverted. She took up with persons in a lower station of life, and would attempt to bring them into her father's house. She scandalised her religious acquaintance by using profane and improper language. If she had any sympathies, they appeared to be with the low and the bad. Respectability in any form she seemed to resent. To strangers, "when she liked," she could appear attractive and amusing. She made an onset on a stout farm labourer, secured his affection, married him, and was never heard of again in her own "set." But hard farm work, the bearing of children, and the responsibilities of life seemed in a way to mitigate some of her social and moral eccentricities. This young woman had a brother who was an epileptic, and several other near relations who suffered from marked neurosis.

I have known hundreds of cases of which the following is a typical example. A young man of 20, of neurotic parentage, of a gay, pleasant disposition, and who was especially noted for avoiding any disagreeable tasks or unpleasant duties, of an artistic temperament and very social disposition, began at 20 to indulge in taking too much alcohol. At first he did so in a social way with his companions, but within two years he had acquired such a craving for it that he had no control over his impulses, and got it in any circumstances and at any price. Bouts of drinking came on him at periodic times, with intervals when he was almost free from the tendency. His whole moral life was changed and deteriorated. His work could not be depended upon, his sense of duty was reduced almost to nil, and he was unfit to continue the profession which he had entered. By 23 he was a typical dipsomaniac, a drunken, useless, and a most harmful social unit, a curse to society, and a disgrace to his connections and friends, his will power gradually getting weaker until he became somewhat silly before he drank himself to death at three-and-thirty. Such cases, which I have called "developmental dipsomania," form by far the most frequent type of this disease, and abound in society, especially in the families of the neurotic, the hypersensitive, the artistic by temperament, and also in families of a certain religious type. A few of them —a very few—recover after full development has taken place, from 28 to 35, but by that time, in most of them, the brain has sustained irreparable alcoholic damage in its highest centres. What might have been if the law allowed us to send them early enough to islands where whisky is unknown, to hard work in the fresh air, to a good moral atmosphere, where strict discipline of life could be enforced, we cannot tell, for such counsels of perfection are at present impossible. The law allows every British subject to drink himself to death if he can pay for his liquor, and we doctors are laughed to scorn if we mention the word disease in connection with such cases.

There is another adolescent risk somewhat similar to the drink craving, which is often seen among the lower classes of society. It is that of what I have called "adolescent criminality." It is a fact that by far and away the greatest number of first convictions of crime—I think they amount to 85 per cent.—take place before the age of five-and-twenty. When the hereditary and the physchological peculiarities of such criminals are carefully studied we find that they come from the criminal, the neurotic, or the degenerate classes. Their great peculiarity is the arrested development of the quality of mental inhibition, hence their fall into the temptations of vice and criminality. I knew a lad once who came of a poor and physically degenerate stock. He received a good education for his class, was subjected to religious instruction, but at 17 fell into the ways of a thief, was detected, and sentenced to imprisonment. From that time he was a habitual and acute thief all his life. He had a high arched palate, a squint, badly formed and placed ears, a somewhat silly expression of face, and his muscular movements were ungainly and improperly co-ordinated. He was, in fact, a moral and physical degenerate, whose chief mental weaknesses had developed in adolescence. He represents thousands of criminals who become so from the same cause.

The patients who suffer from those various mental deficiencies which place them in this section do not necessarily exhibit any outward bodily peculiarities or any stigmata of degeneration. Some of them are well grown, symmetrical in form, and with a good expression of face and eye, though others, no doubt, are asymmetrical in head and face, with high vaulted palates and unpleasant expressions.

It may seem far fetched, but I am quite convinced that many of the precocious youths of both sexes who give great promise up to 15 or 16, and then fall into stupid, lazy ways, and are no good at any real work of life afterwards, being really below the average of their age and class in real intelligence—that most of this class, too, may be reckoned as examples of adolescent mental risks.

Looking to the cases in this section of minor adolescent risks, it is very difficult to speak as to a prognosis of their future. Some of them are curable, recover, and do their work in life fairly well, a few even becoming brilliant examples of men and women; but most of those who recover are, on the whole, below the average of their class in regard to their success in life, and are unreliable. A large number, again, are incurable, and become the eccentric, the cranks, the shiftless, the drunkards, and the criminals of society.

The next section of adolescent mental risks of which I would speak are those who remain mentally normal until they have passed 20 years of age, and then for a few years become subject to attacks of depression of mind. Some of them, where such attacks are mild, where the self-control is not decidedly impaired, and where there are no suicidal tendencies, are not ranked among the technically insane. Some again, where the attacks become more acute, where they cannot control or look after themselves, where suicidal impulses arise, pass beyond the line of sanity, and are treated as suffering from mental disease. A good example of this form of mental risk is the following:—A young lady of three-and-twenty, whose father and mother were both able but markedly neurotic, but where no actual technical insanity was proved to exist among ancestors or collaterals, had worked hard at school and college. She was a keen, sensitive girl, with high ideals, and a large capacity for unselfish deeds. By the way, there had been a fair amount of consumption among her ancestry, and she had a brother who fell into that disease. She took an attack of influenza, and from that time her nervous energy was evidently sapped. She never regained her sleep, her appetite became poor, she lost flesh, and in a few months was in a state of distinct melancholia, suffering mental pain in an intense form, very sleepless, very restless, and incapable of looking after herself. She was introspective to a morbid degree, and accused herself of all sorts of evil deeds of which she certaintly had not been guilty. She tortured herself by exaggerating her real and imaginary failures of duty. She was sent to the country with a sensible relation and a good nurse, was made to live in the fresh air all the time, was fed on milk and fattening diet, was encouraged and almost compelled to occupy herself in various ways, and in about four months seemed to have recovered. But within the next three years she had several lesser relapses into the same condition of melancholia, thus exhibiting the periodicity which almost all the adolescent neuroses are more or less characterised by. Before she was 26 she made her final recovery, regaining flesh and spirits, looking much more womanly than before she took the attack in appearance and manner. She was not sent back to study, and for many years, and so long as I could trace her, she was well, and led a normal family life. Her case is very typical of this section of mental risks during adolescence. Apparently, she almost escaped mental neurosis, but the influenza acted as its exciting cause. Had she been a girl without means she certainly would have had to be certified, and sent to a mental hospital. She was undoubtedly insane in the medical sense part of the time of her first attack. The prognosis in such cases is good, and the treatment is what I have indicated. This section represents mental disease as technically understood in its first stage, and when it appears for the first time in a family the nervous temperament which had existed in ancestry had, through the marriage of two persons of the same diathesis, become accentuated into melancholia, and the age of adolescence and development was the most defenceless time of life on the part of the mental cortex.

The third section of adolescent mental risks represents a still stronger tendency to actual insanity. It is the one which is characterised by maniacal attacks usually of an acute character, periodic improvements and relapses, but, above all, by the tendency of many of the cases who suffer from it to pass gradually, after a number of maniacal attacks, into that most terrible of all mental conditions, Secondary Dementia, which represents a premature mental death with the ordinary bodily functions remaining to a large extent intact, and with the capacity for more or less continuous life for many years. In the year 1873 I studied this condition, described it, and called it "Adolescent Insanity," a term which has come into general use since then. Of late, Kraepelin and many other German and American psychiatric authors have described a considerable number of the cases of it under the term "Dementia Præcox." I find no fault with Kraepelin's descriptions, which are for the most part true to nature; but I would object to the number of varieties of Dementia Præcox which he has set up, because I believe they do not represent permanent facts in disease. He has divided Dementia Præcox into "hebephrenic," "paranoic," and "katatonic" varieties, and has otherwise elaborated his descriptions, so that a large number of the cases of adolescent insanity would be excluded. I strenuously object to the term "Dementia" being used to denote any curable variety of insanity, and Kraepelin admits that some of his cases of Dementia Præcox recover. I also say, without fear of contradiction by any experienced psychiatrist, that in the early stages of many of the cases it is quite impossible to say whether they are going to recover or to become demented. I also aver that Kraepelin's varieties often pass into each other as different phases of the brain disease in the same case. I agree with Dr. Lewis Bruce that many of the cases are of toxic and bacterial origin as the immediate and exciting cause of the mental symptoms; but I am quite sure that behind, and of more importance than the toxic and the bacterial causes, is the innate hereditary weakness in all those cases which exhibits itself during the momentous period of adolescent brain development. In a very few of such cases, the disease begins at puberty, in a large number between puberty and eighteen, and in by far the largest number between eighteen and five-and-twenty. The mental changes that take place between eighteen and five-and-twenty in the human brain are incomparably more important than those which occur between puberty and eighteen. Take the following as a typical instance of this section with which I am dealing:—A student of 23, who had worked hard, whose mother had had puerperal mania after almost every child she had had, and had been latterly epileptic, his father nervous, two sisters and one brother having attacks of mania subsequently to his own. In addition to his hard study and a sedentary life, he had been given to evil sexual habits. He suddenly became morbidly exalted, sleepless, talkative, restless, and was soon violent and unmanageable—was, in fact, suffering from an attack of acute, almost delirious, mania. His temperature was over 100 degrees, he was sent to Morningside, and lost, through his excitement, 28 lbs. in the first six weeks. All kinds of sedatives were tried, temporarily in vain. After about two months the intensity of his mania abated, but his expression of face became enfeebled-looking, his habits degraded, and it seemed as though he were to pass into dementia; but by means of careful and brain-stimulating treatment, he slowly recovered, more than regained the weight he had lost, and became, to all intents and purposes, a sane man. But after going back to city life, he had various domestic trials, and became insane again in eighteen months. He passed through another attack of mania, and recovered. He then had a third attack, and as the excitement abated he passed into that bourne of mental death from which no patient ever returns, and he remained during the rest of his life a mindless dement. Let us now look at a case with somewhat the same symptoms, but the termination of which was more fortunate, a lad aged 21, an intelligent and hardy fisherman, a ruddy son of the sea. At first he behaved as though something were preying on his mind, in which he suffered from a sort of mild prelude of sane depression. This soon passed into an elevated and maniacal condition of brain, and lasted for a week, and he then appeared to get well. In a few weeks he again became maniacal, and in ten days became rational and quiet. After a few months he appeared to get quite well, left the hospital, and he looked a full bearded young man, apparently several years older than he was on admission. This process of completed bodily development connected with improvement of mental symptoms, I attach great importance to. It means, I think, that Nature has completed her work in building up the man and woman, body and brain. When it is connected with recovery it is a good sign; when it is connected with threatening dementia, it is a bad sign. This young man's heredity was extremely neurotic. He came of a family where among ancestry and collaterals there had been insanity, epilepsy, idiocy, and phthisis in a large number of cases. He resumed his work, earned his livelihood, and has had, in the 20 years that have elapsed since I first knew him, one maniacal attack from which he soon recovered. He has married a wife, begotten children, and no doubt has thus handed on his nervous adolescent risks in an abundant degree to future generations.

The treatment of all such cases should be in principle supporting and non-stimulating, with plenty of occupation and fresh air. I would not say but what there are a few who need rest in bed in the early and very acute stages. Dr. Lewis Bruce has given us in his "Clinical Studies in Psychiatry" very careful and most instructive observations and studies in regard to the blood condition of such cases. He shows that in some there is a persistent hyperleucocytosis, and in others a fall in the number of leucocytes to below 8,000 cmm. of blood. Where the leucocytes tend to fall unduly, and do not rise in number even during a tendency to brain excitement, he says the prognosis is bad. He also shows that in many of the cases who recover, they have a persistent hyperleucocytosis, which shows that against the bacterial invasion to which they are subject, there is going on all the time the formation of antibodies to counteract their evil effects.

As a statistical fact, the mental risks of adolescence are so great that 75 per cent. of the chronic insanity now existing in the country result from them. Almost all the typical secondary dementia, and most of the delusional insanity arise out of, or have as a preliminary stage, attacks of adolescent insanity.

Note.—*A Clinical Lecture by a well-known teacher appears in each number of this journal. The lecture for next week's issue will be by Macleod Yearsley, F.R.C.S.Eng., Senior Surgeon to the Royal Ear Hospital, London, the subject being "Chronic Non-Suppurative Diseases of the Middle Ear." A post graduate lecture.*

The annual dinner of the Incorporated Society of Medical Officers of Health was held on January 11th in the Holborn Restaurant. Dr. D. S. Davies, medical officer of health for Bristol, presided, and the company numbered about fifty.

ORIGINAL PAPERS.

THE HISTORY OF OVARIOTOMY. (a)

By F. BOWREMAN JESSETT, F.R.C.S.ENG.,
President of the British Gynæcological Society; Surgeon, Cancer Hospital, Brompton, &c., &c.

THIS, in all probability, will be the last valedictory address which will be issued from this chair to the Fellows of this Society, as Fellows of the British Gynæcological Society. I think the Society can congratulate itself upon the work it has accomplished since its formation. Before the seventies and early eighties of the last century, little was understood respecting the diseases peculiar to women, and their surgical treatment. In 1884 a small band of earnest workers met with the object of forming a society for the promotion of the study of gynæcology, among them Drs. Robert Barnes, Lawson Tait, Meadows, Aveling, Routh, Granville Bantock, Heywood Smith, Edis, Lloyd Roberts, Travers, and Mansell Moullin. Of these our hon. president, Dr. Robert Barnes, Dr. Routh, Heywood Smith, and Mansell Moullin are the only survivors. The idea was to make the new society as cosmopolitan as possible, and it was decided that it should be named the British Gynæcological Society.

The Society was registered under the Companies Acts of 1862 and 1883 as an "Association for the promotion of the study and science of diseases of women by means of meetings, lectures, records of practice, and a journal of transactions, and by other lawful means." The Memorandum of Association was deposited on February 14th, 1885, and the Association duly registered on March 4th, 1885, so that you see the Society has completed its majority.

The British Gynæcological Society, when the final ceremonies of marriage with her cousin, the Obstetrical Society have been duly gone through, and the Register signed, will sink her present name, and in future will appear as "The Obstetrical and the British Gynæcological Society." I have said she will sink her name, but not her identity, for I am sure there are many Fellows who will, by the work they bring before the new Society, uphold the traditions of those Fellows who have done so much during the past twenty-two years, by earnest research and hard work, the results of which have been presented in the shape of papers read at the meetings, the exhibition of specimens, and by the Journal in which will be found all papers reproduced and discussions. Besides this, a most valuable collaboration of all available reports of gynæcological work throughout the world is contained in the Journal, which reflects the highest credit upon the industry and energy of the various editors and their staffs.

In this address I propose limiting my remarks to the history and progress of Ovariotomy and the Treatment of Tumours of the Uterus.

OVARIOTOMY.

The question of dealing with ovarian cysts appears to have been discussed as long ago as the eighteenth century, but does not appear to have got any further than discussion. In the year 1762, Dr. William Hunter published a paper on "Cellular Tissue," in which he says: "It has been proposed by modern surgeons of first repute to attempt a radical cure of ovarian cyst by incision or suppuration or by excision of the cyst." Having pointed out the difficulties and dangers following this, he concludes with these words, which foreshadow some of the recent modifications in the operation:—"If it be proposed (he says) to make such a wound in the belly as will admit two fingers or so, and then tap the bag and draw it out so as to bring its root or pedicle so close to the wound in the belly that the surgeon may cut it without introducing his hand, surely in a case otherwise so desperate it might be advisable to do it, could we know beforehand that the circumstances would admit such treatment."

Later, John Hunter, in a lecture delivered in 1785, says:—"I cannot see any reason why, when the disease (ovarian dropsy) can be ascertained in an early stage, we should not make an opening into the abdomen and extract the cyst itself. Why should not a woman suffer spaying without danger as well as other animals do?"

It was not, however, until the year 1809 that McDowell, a Virginian, who had attended a course of lectures delivered by John Bell, of Edinburgh, performed the first ovariotomy in Kentucky. So successful was he that he is reported to have lost only one case—the last—in five women on whom he operated.

In the year 1823 Dr. James Blundell, having made a number of experiments on the rabbit with the object of improving the surgery of the abdomen, and observing the toleration of the abdomen in man when wounded by accident or design, came to the conclusion that a moderate opening into the human peritoneum would not necessarily, nor even generally, prove fatal from inflammation or otherwise, and, further, that certain viscera, or parts of viscera not essential to the welfare of the structure may be removed from the belly without necessarily or even generally causing death. He therefore proposed that the following operations might be performed:—

Division of both Fallopian tubes.

The extirpation of healthy ovaries in dysmenorrhœa and menorrhagia.

The extirpation of ovarian cyst in scirrhus. This operation, he says, he is persuaded will come into general use.

The removal of a large circular piece of the cyst in ovarian dropsy when the sac cannot be extirpated.

The removal of the cancerous womb.

Extirpation of the puerperal uterus when Cæsarian section is performed.

In rupture of the bladder, lay open abdomen, tie bladder, discharge urine and wash out the peritoneum thoroughly by injection of warm water.

Lizars, of Edinburgh, appears to be the first to attempt ovariotomy in this country. In 1827 he performed two operations, the first successfully, the second died in a few hours, while Dr. Granville is recorded to have operated in 1836 in London on two cases. The first case was abandoned on account of adhesions; the second, a fibrous tumour was found and removed, the patient dying on the third day. The results were so disastrous that the operation seems to have fallen into abeyance until 1842, when Dr. Protheroe Smith and Dr. Clay, of Manchester, operated on several cases successfully. But it was not until 1846 that the operation was performed successfully in a London hospital by Cæsar Hawkins. Mr. Hawkins did not repeat the operation, and only one or two surgeons in London, Dr. F. Bird, Mr. Lane, and Dr. Protheroe Smith, who had successful cases, attempted it.

In 1850 Dr. Duffin inaugurated a new era in ovariotomy by raising the question of the danger of leaving the tied end of the pedicle in the peritoneal cavity, by insisting on the importance of keeping the ligatured stump outside. In only one case is he reported to have adopted this procedure, and in this he found he could only stitch the cut extremity to the wound; it answered admirably. There can be no doubt, as Sir Spencer Wells has said, that this argument of Duffin's led to great changes and results, to the use of the clamp and to all modifications, and ultimately to researches as to the physiological and pathological phenomena of ligatured stumps within the peritoneal cavity and to the study of the subject of drainage.

In 1853 Spencer Wells first commenced work in London, and in the following year joined the Samaritan Hospital. Baker-Brown at the same time was operating, but with poor success, and for the following four and a half years he did none, saying that peritonitis was sure to beat one.

It was not until 1856 that Spencer Wells, having returned from the Crimea, where he had been engaged in war surgery, began seriously to pay his attention to ovariotomy. Baker-Brown had given up the operation, very few were attempting it, and most men were lapsing into the old state of indifference, if they were not loudly protesting against it. I will not trouble you with the different methods of dealing with the pedicle adopted in these days. Some adopted ecraseur, cautery, or whipcord ligatures, the ends hanging out of the wound, but the clamping was the most usual way. The death-rate still kept very high—as much as from 20 to 25 per cent. It is undoubtedly due to Spencer Wells that ovariotomy became recognised as an established operation. Until the year 1877 he had performed 408 operations with a mortality of 99 cases, about 25 per cent., but during the last two or three years the mortality was only 10 per cent. Lawson Tait was at this time also busily at work.

(a) Abstract of Valedictory Address to the British Gynæcological Society, January 10th, 1907.

In the year 1877 Lister came to London and introduced his system of antiseptic surgery with the carbolic spray. Wells hesitated, but Knowsley Thornton introduced the new practice into his wards, and Bantock for a time followed his example, abandoning it later for absolute cleanliness. It may not be uninteresting here to give Wells' table of his series of cases during the first twenty years of his practice, showing how experience and more care in technique reduced his mortality from 30 per cent. to a little over 9 per cent.

	CASES.	DEATHS.	RECOVERIES	
First five years, 1858 to 1862	30	9	70 %	successes
Second five years, 1863 to 1867 ..	83	21	74 %	,,
Third five years, 1868 to 1872 ..	133	36	73 %	,,
Fourth five years, 1873 to 1877 ..	162	33	80 %	,,
Last two years, 1876 to 1877	71	7	90 %	,,

Billroth, who had been operating in Germany from 1865 until 1884, had performed 327 operations, 101 of which had died, a mortality of 31.5 per cent. In his remarks upon his cases he says :—

" *Granted that the operation is well done, and that the patient does not die within about twenty-four hours from loss of blood or shock (which has occurred to me only four times in 222 cases), the result depends upon whether the sponges, fingers, instruments, secretions, and, above all, the ligature threads are clean.*"

Sir Spencer Wells claims long before Lister had tried any of his methods—indeed, from the very beginning of his practice—to have insisted upon all possible care in protecting patients before, during, and after operation from all known causes of excessive mortality. Yet his mortality was terribly high in comparison with that of gynæcologists of the present day, as, although he adopted strict antiseptic methods, as prescribed by Lister in those days, viz., carbolic spray during the performance of the operation, antispetic dressing to the wound after, and all instruments, sponges, ligatures, etc., being placed in carbolic acid solution, he lost from 1878 until 1884 out of 247 cases, 27 patients, making a mortality of 10.9.

That this high rate of mortality was due to a very great extent to faulty after-treatment, and not to any errors in technique in the mode of operation, I think must be generally admitted, and it is due, I think, very much to the suggestion of Lawson Tait, who startled the profession by advocating large doses of magnesium sulphate for the treatment of peritonitis, that operators began to have better results after all abdominal operations. Previous to this, after ovariotomies, myomectomies, &c., patients were given opiates by the rectum or mouth if there were not much retching, the object being to keep the bowels quiet, and it was a dictum that they need not act for ten days or more ; Spencer Wells states a case in which they did not act for nineteen days, and then acted naturally. Now, although Lawson Tait recommended the aperient treatment for peritonitis in cases after abdominal operation, it was a misnomer, as the cases undoubtedly were not those of peritonitis, but of distension of the intestines due to paresis of the bowel, and many of those patients who died lost their lives not from peritonitis, as supposed, but from exhaustion due to vomiting, pain, and possibly septic absorption due to this over-extension of the bowel.

It has now long been recognised that the bowels should be relieved by aperients and enemata within forty-eight hours of the operation being performed.

The results, then, of the operation for removing ovarian tumour, were even up to the early eighties not such as to encourage one very much. However, we know now that the mortality after this operation by improved technique and after-treatment is reduced to from 2 per cent. to 1 per cent.

TREATMENT OF UTERINE TUMOUR.

In 1887 Lawson Tait brought before the Society the importance of washing out the peritoneum after certain operations, with a view of cleansing, in the place of doing so by sponging, as he had a dread of sponges, looking upon them as a most efficient means of carrying infection with which he was acquainted. This and drainage, like many other forms of treatment, had practically dropped into disuse, excepting in cases where there has been some escape of pus, or in which many adhesions had been torn through, and there had been considerable oozing, it is thought necessary to either flush the peritoneum or drain. In any case, the glass drainage tube, like the " serre nœud," is now a thing of history.

How different are the results at the present time, when in skilled hands the operation of hysterectomy is performed with a mortality of less than 5 per cent. This happy result is due no doubt to several causes. The operation being acknowledged as a most successful one, patients suffering from uterine tumours are advised to have them removed early, before their strength has been reduced by constant hæmorrhage or life made unendurable owing to the pressure of these large tumours. The insistance of having the patient properly prepared, the abdomen thoroughly cleansed with antiseptic solution, all instruments boiled and sterilised. The use of properly sterilised swabs during the operation, as well as all dressings to be applied after the operation ; dressings are not disturbed for a week or ten days after the operation. The care taken by the operators to thoroughly cleanse their hands, and the administering of an aperient to the patient twenty-four hours after the operation. The adopting the position as suggested by Trendelenburg, of placing the patient in an inverted position by means of elevating the pelvis during the operation, so as to allow the intestines to gravitate out of the field of operation. The use of Doyen's retractor, by which a much better view of the floor of the pelvis can be obtained. The attention to smallest detail, arresting all bleeding, and the careful stitching of the peritoneum over the floor of the pelvis, care being taken to bury all stumps to which ligatures have been applied. The care which is now taken in closing the parietal wound in layers is a most important innovation of late years, whereby the risk of hernia of the wound is reduced to a minimum.

The question of removal of the uterus for malignant disease has always been a source of anxiety to surgeons. So far back as 1828 Blundell proposed excision of malignant uterus per vaginam. He carried out this operation in four cases, three of which proved fatal, two within six hours of the operation, one after thirty-nine hours, and one lived a year. To Dr. Purcell is due the honour of having performed vaginal hysterectomy for cancer of the uterus first in this country at the Cancer Hospital in 1883. The operation had been performed on the Continent by Freund, Olhausen, and others, but with very meagre success. Out of ninety-four cases commented on by Oldhausen, only twenty-four survived. I performed the operation in 1886 on three cases, two of which died from peritonitis, and the third made a very tardy recovery. Since that time I have performed the operation in over 200 cases, and the mortality is so low, and the patients convalesce so well, that I am still an advocate for the operation in preference to the abdominal operation in certain cases. As time advances and science and practice improve, so do old operations become superseded by new, and I know the Americans and Germans and many British surgeons now almost invariably remove the uterus for cancer through the abdomen, whether with more favourable results, I think is still open to question.

Although the Hunters suggested the feasibility of opening the abdomen for the removal of ovarian cysts, little did they dream of the far-reaching results which were to follow the perfecting of that operation—the removal of suppurating tubes, the study and treatment of ectopic gestation, Cæsarian section, all connected with gynæcology, and then the extension to intestinal surgery, the surgery of the liver and kidney—verily, what a monument is perpetuated by the surgery of the abdomen alone, which has attained such brilliant success, to the discovery and research of those two great and distinguished men, Sir James Simpson and Lord Lister.

TETANIA PARA-THYRO-PRIVA.

By Prof. JAKOB ERDHEIM, M.D.,

University of Vienna.

THE history of tetania after the removal of the thyroid gland begins with the name of Nathan Weiss in 1880, who was a member of Billroth's Clinic at the time, and who had commenced the entire extirpation of the thyroid for the radical cure of goitre. Three years later Reverdin and Kocher, for the first time, noted the sequence of cachexia strumapriva. These observations arrested the attention of physiologists, and gave the first proof of a long-hidden conjecture that these ductless glands had some connection with the due elaboration of the blood. Tetania strumapriva connected the function in some way with the nerve system, and led Schiff, Wagner, and Eiselsberg in the following year to make experiments with animals to prove the veracity of the statements whose labours confirm the truth of a pathogenic tetania. Further progress in the knowledge of tetania remained in abeyance till 1890, when Gley again gave a new impetus to the investigation by declaring that Sandstroem had discovered the active principle or functional agent in the gland, which he named glandulæ para-thyroidæ, epithelial bodies, or vesicles found in the yellow fluid that exudes from the gland when cut. Gley further affirmed that this gland was in sympathy with the hypophysis cerebri or some portion of the brain near the sella turcica. This conclusion was drawn from the inference that thyroectomy was better borne by animals that had large hypophysis cerebri than in those that had small organs. Hofmeister affirmed that the enlargement of the thyroid was only a vicarious expression of the hypophysis, and that the origin of the disease was central. The function of the gland was then attacked. Was it athyrea, hypothyrea, or dysthyrea that influenced the gland in the second place? Idiopathic athyrea, or loss of secretion, caused the gland to atrophy; but the symptoms were different in such cases in being slow and degenerative, and without tetany, which was usually present in hyperthyrea if the gland were removed. Rehn held to a dysthyrea or alteration in the quality of the secretion as the true cause. Closer investigation and comparison soon arranged Basedowi, cretinism, and chrondro-dystrophy as allied diseases, though symptomatically expressed in different shapes.

Vassale and Generali next commenced a series of experiments on dogs, founded on the assumption of Reverdin that a para-thyroid body existed in man, as well as in fishes and other mammalia. The entire gland was removed in one portion, and partially in another. When the whole gland was removed tetany invariably followed; when partially removed this was not so constant on the cachexia. This lead to closer investigation of the anatomy of the organ by Kohn, who discovered the large epithelial bodies in the gland which have now received the classic distinction of glandulæ para-thyroidæ. On closer inspection they found that these para-glandular bodies were the active agent in the prevention of the tetany when not injured, but when destroyed the tetany appeared. These experiments were confirmed by Walbaum, Pineles, and others, who removed the glandulæ para-thyroidæ alone and obtained the tetany, but when they extirpated the entire gland no tetany was observed, but the cachexia was pronounced.

At this point of the history Erdheim commenced his own experiments on rats by destroying the epithelial bodies with the galvano-cautery. Fifty animals were operated on in different ways, some partially, others complete para-thyroidectomy; some partial thyroidectomy and others complete thyroidectomy. The result proved that complete para-thyroidectomy—*i.e.*, where all the epithelial bodies were destroyed, but the gland substance retained, produced tetany; but in cases where some of these epithelial bodies were preserved in the gland, tetany was absent. In the latter cases of partial para-thyroidectomy, the nerve disturbance was in proportion to the number of epithelial bodies left; if few, the tetany was more severe than in the cases where a greater number were destroyed. In the cases of total para-thyroidectomy, the animals usually died within two to five and a half months from severe cachexia, as a result of inanition. The real cause of the inanition seemed to be the inability to take food, due to some trophic disturbance of the teeth. This trouble usually appeared about the sixth or seventh week after the operation, when the teeth began to break and fall out. The histological examination showed that the changes were mostly in the dentine, which became dry, brittle, and chalky about the tenth day after the operation without any real local cause.

This trophic disturbance has not hitherto been observed, or described, in experimental tetany, as far as laboratory work is concerned, and it may be of interest to follow in the trophic changes in man where no such changes have yet been recorded. The falling-off of the hair and the nails was apparently associated with the decay of the teeth, and resembled in many respects the exhaustion or decay witnessed in old age. Erdheim also observed cloudiness of the lens in the tetanic rats not before recorded from the laboratory, although cataract has been observed to succeed tetany.

Like other laboratory experiments, our reasoning has to be modified in the dog. According to Gley, only two of these epithelial bodies can be met with in the dog, although Kohn affirms there are four. Be this as it may, Erdheim obtained very different results in the dog than in rats. In the latter he always obtained tetany; in the former never once. In rats he found many of these epithelial cells in the neighbourhood of the thymus, and, struck with the rarity of them in the thyroid, his curiosity led him to investigate this region more carefully. Laying the neck bare, he found ten of these epithelial bodies around the margin of the thymus accessories in one, and 32 in another dog. These were strewn throughout the thymus as well, in all sizes, so that their function must not be neglected in determining the results. These facts may account for the absence of tetany in dogs, but they do not invalidate the hypothesis that the cause of tetany rests in the epithelial bodies. It is safe to presume that the operations on the human subject bear this interpretation, that some surgeons have removed different numbers of these epithelial bodies and obtained different results. Although the assumption of some special agent has been accepted, no surgeon hitherto has been able to demonstrate this active part in the gland, which may be termed para-thyro-priva, and is the principal cause of the tetany. With this proof in view, Erdheim performed three operations on the human subject of partial strumectomy on both sides of the gland, which produced the typical tetany. The first died four months after the operation from tetany of an epileptiform character. The second case died after five months; the third in seven months in a similar manner to the first.

The post-mortems gave very little information, as the morbid changes were few beyond lobar pneumonia, with cloudy swelling and œdema in the lung tissue. All the other organs were healthy. The examination of all the epithelial bodies in the gland could hardly be undertaken from their number, as they would exceed thousands of incisions, but in all the three there were a large number of healthy corpuscles not necrosed, although one of them had the principal ones destroyed, as well as that in the thymus and small accessories. In the second only one epithelial corpuscle was destroyed, and in the third neither the principal nor the accessories were present. The experiments were in accordance with the theory after extirpation of tetany being produced by the necrosis of the epithelial corpuscles, although a large number were preserved in a healthy condition. These conclusively prove that extirpation of the gland produces para-thyro-priva. When it is assumed that tetany is a rare occurrence in total extirpation of the gland in the human subject, we must modify the assumption to a part of the gland being removed, and that the principal epithelial corpuscles have been preserved. It is generally admitted that tetany is not so frequent since the operations have been confined to partial removal of the gland, as more of the epithelial corpuscles must have been preserved. Unilateral operations have been quite as successful in many cases as the partial removal of the gland where a compensatory hypertrophy of the epithelial corpuscles has taken place in the residuum.

The most important question for practical solution is how to preserve the epithelial bodies in operating. This is difficult in human subjects, as their position is variable and topography uncertain. None of the operations hitherto have been free from tetanic attacks, though not so frequent as stated above. At this point Erdheim showed several preparations where the recurrent nerve on both sides with the epithelial bodies had been carefully observed, as these latter are often found near or over the recurrent nerves. The best operations seem to be those practised by Mikalicz, which is a wedge resection, and Kocher, who practises enucleation resection. Both of these operations leave the recurrent nerves and their coverings intact. It is true that Billroth early acknowledged the preservation of the recurrent nerves, and carefully dissected them from the gland before its removal, but his efforts met with no better success owing to the removal of the epithelial bodies.

In supporting this theory we have other conditions in the gravid state to reconcile with these epithelial bodies. If an animal in the gravid state have these bodies disturbed, severe tetanic convulsions occur; but where there is no pregnancy the tetanic phenomena are absent. Again, after removing both of the principal epithelial bodies, severe tetanic cachexia set in, but no pregnancy ever took place. To obtain an exact relationship between the gravid uterus and the insufficiency of the epithelial bodies, it was necessary to destroy one of these, leaving the rest intact, while other experiments were conducted with partial lesions. From four animals treated according to the first method, three of them became gravid, two dying from tetany in pregnancy. Twenty other animals were treated by removing half of the epithelial bodies; 14 of them became gravid, of which ten were only once, two were twice, one three times, and one four times; but in all of the cases they ended with tetany, commencing in the last third of pregnancy, and continuing to parturition.

There is another symptom that should be noticed in conjunction with the tetany—viz., the falling out of the hair. It is a premonitory symptom, and is to be observed in the human subject as well as animals. This theory of Erdheim is at variance with Pincle's explanation, who maintained that the tetany was always synchronous with a recurrence of the increase in the residue of the gland, which he presumed was due to pressure on the remaining epithelial bodies. This hypothesis presumes that the epithelial bodies become hypertrophied. In connection with this might be quoted one of Billroth's cases in 1886, where a woman, æt. 36, had the thyroid entirely extirpated on account of adenoid tumours. All went well in the clinic after the operation, but after her return home she developed tetanic symptoms resembling the contractions in pregnancy. Later this phenomenon gave way to a chronic cachexia. In 1887 she became pregnant, with the typical symptoms renewed. In 1888 she again became pregnant, with a hard tumour appearing behind the manubrium sterni. During the latter period the cachexia had disappeared, and always about the period of the menses this tumour increased. In 1891 the tumour became very active, and increased enormously, giving great pain, so that in September, 1892, she returned to Billroth's clinic, where it was diagnosed as a sarcoma, probably malignant. In the neck there was no trace of the thyroid gland. It was resolved to resect the tumour, and when examined, was found to contain carcinomatous cylindrical cells or malignant adenoma. In the cell trabecula colloid matter was found, which confirmed the opinion that the neoplasm was a cancerous struma metastasis. On the ninth day after the operation, tetanic symptoms again set in, but soon improved. After some time cachectic symptoms appeared. About this time a knobby tumour commenced to grow below the scapula, which was diagnosed as a metastatic growth. During this time the patient was otherwise quite well. In November, 1893, she bore a healthy child, and shortly afterwards died from cachectic symptoms. In this case the tumour behind the sternum must be acknowledged as an accessory epithelial body, which vicariously became hypertrophied and performed the necessary hæmopoetic or hæmatosis in the sanguinary system.

From Billroth's other cases to the year 1890, he relates twelve of tetany after total extirpation. Five of these were "Foudranter tetany," two chronic that died, two which lingered long, and one that recurred.

During the last five years 356 cases have been operated on, with 16 giving symptoms of tetany; 11 slight in the face, two continued some time, while the others were easily cured with thyroid gland. It may be assumed that better results have been obtained in the extirpation of this gland where care has been taken to preserve the recurrent nerves and tie the inferior thyroid arteries, which points to the preservation of a greater number of the epithelial bodies which usually lie round these parts.

The methods that have given the best results in this respect are:—Socin's enucleation, Kocher's enucleation resection, and Billroth's half to four-fifths extirpation.

In connection with this compensating theory, Paltauf found in goats, which he had operated on to produce struma-priva for the treatment of Basedowi patients, that the isolated epithelial cells were greatly hypertrophied and of a dark red colour when examined in the post-mortem room.

There are difficulties in our theory common to all assumptions founded on clinical experience. If the "insufficiency" of the epithelial body is the cause of tetany, Kassowitz has pointed out that the tetany of the rachitic child will be due to the same cause, although it may be of an idiopathic nature, and not operative These attacks are more frequent than in the adult, commencing in the winter months sporadically, but very frequent in the months of March and April, disappearing altogether in the summer and autumn. In all these cases testimony of rachitis will be present in the bones of the head, but the child seems to recover with the season, probably from obtaining more fresh air. If an adult, the same clinical history is experienced. The question is: Can this be a lighter form of the new-born theory? In all the forms we must admit the convulsions arise from a toxine on the centre, which cannot come from the same source. In the experimental or operative, the toxic action would be endogenous from the epithelial bodies being destroyed, which neutralise the poison that acts on the trophic nerve and induces the convulsions. On the other hand, the poison seems to be from without, which we may term a respiratory noxa passing from the periphery along the nerve trunk to the centre. This may explain the prompt action of phosphoric medication, which allays the rachitic, but has no effect on the purely neurotic. In the former it seems to modify the cranial rachitis and reduce the collateral hyperæmia in the cortical centres. The exogenous noxa is neutralised by open air, generous diet, and careful hygienic attention.

THE HÆMO-RENAL SALT INDEX

AS A

TEST OF THE FUNCTIONAL EFFICIENCY OF THE KIDNEY (a).

By DAWSON TURNER, B.A., M.D., F.R.C.P.Ed., M.R.C.P.Lond.

Lecturer on Physics, Surgeon's Hall, Edinburgh.

The author first briefly described the methods employed for determining the electrical resistance of the fluids, and demonstrated an apparatus he had devised for use with only 5 cubic millimetres of blood, instead of the 5 or 6 cubic centimetres generally required. He had compared systematically the electrical resistance of the blood and of the urine in a large number of medical and surgical cases, and had originated a term expressing the ratio between the two, to which, after consultation with Dr. George Gilson, he had given the name "Hæmo-Renal Salt Index." In health this index is equal to 3, 4, or 5, whole numbers, thus :—

$$\frac{\text{Electrical resistance of blood}}{\text{Electrical resistance of urine}} = \frac{900}{225} = 4$$

The higher the hæmo-renal index is, the healthier, other things being equal, is the patient. If the index increases it indicates that the blood contains fewer salts, or is richer in corpuscles (which, as Professor Stewart and Mr. M. Wilson have shown, obstruct the passage of an electric current), and that the functional activity of the kidney is increasing. If the hæmo-renal index diminishes then the kidney is becoming sluggish and less efficient. Experiments on artificial urines, made of solutions of urea and sodium chloride in distilled water, had shown that the salt was the main factor in influencing the electrical resistance of the urine. Reference was next made to a number of cases, and particularly to some medical cases, whose hæmo-renal indices had been examined from time to time over periods of more than two months ; he pointed out that the hæmo-renal index well reflected the general condition of the patient, rising with improvement, and falling again with relapses. In diabetes and in pernicious anæmia the electrical resistance of the urine was sometimes very high, giving a low hæmo-renal index. In surgical cases this method of investigating the renal efficiency seemed to be of considerable value, and its indications so far agreed totally with those of cryoscopy. Some surgical conditions in which a successful operation had afterwards been performed were referred to in detail :—(1) Female, æt. 37, under the care of Mr. F. M. Caird. Disease of right kidney. The resistance of the blood was 1060, which is normal. The resistance of the urine segregated from the right (diseased) kidney (4 specimens) was 330 ohms ; urea 5 grs. to ounce, pus cells present. The resistance of the urine segregated from the left (healthy) kidney was 235 ohms ; urea 7.5 grs. to ounce. Hæmo-renal index of right kidney $\frac{1060}{330} = 3.2$; of the left kidney, $\frac{1060}{235} = 4.5$. These indices were very satisfactory, showing that the left kidney was very efficient—nearly one and a half times as much so as the right, and that operation was therefore not contra-indicated. Operation showed that the right kidney, though containing a good deal of kidney substance, was the seat of so many small calculi (practically a mass of sand) that removal of the entire organ was necessary. The result was in all respects satisfactory. (2) Male, æt. 24, under the charge of Mr. Cotterill ; probable disease of left kidney. The resistance of the urine segregated from the right (healthy) kidney (4 specimens, two with indigo carmine) was 371 ohms. ; the resistance of the urine segregated from the left kidney was 675 ohms. The resistance of the blood was 960. The hæmo-renal index of the healthy kidney $\frac{960}{371} = 2.5$—below normal, indicating that kidney was not very efficient. The hæmo-renal index of the left (diseased) kidney was $\frac{960}{675} = 1.4$—far below normal, showing that the kidney was very inefficient. Operation showed that the left kidney was simply a bag of pus ; the patient died about twenty-four hours later. The speaker concluded by remarking that the method was another example of the application of precise scientific measurement to clinical medicine and surgery, and that it was of extreme importance to the medical student to have a proper training in medical and experimental physics.

(a) Abstract of Paper read before the Edinburgh Medico-Chirurgical Society on Jan. 16th, 1907.

THE OUT-PATIENTS' ROOM.

CHILDREN'S HOSPITAL, PADDINGTON GREEN.

Nævus of the Forearm.

By Arthur Edmunds, M.S., F.R.C.S.

Amongst the out-patients was a child (male), æt. 9 months, who was brought with a large nævus just above the wrist-joint. The nævus was situated over the flexor tendons, and extended nearly halfway round the limb. It was irregular in outline, and measured about one inch in the long axis of the limb. It consisted of two portions, one of which was deep to the skin, showing the usual bluish colour, while the other portion invading the skin itself was bright red. The question of treatment, Mr. Edmunds said, presented itself, and one had to consider the best method to adopt. The need for treatment for these cases was, he thought, well shown in another case which was attending his out-patient department, in which a child had been born with a nævus on the right shoulder about as large as the palm of the hand. There had been difficulty in establishing respiration, and in consequence the chest had been rubbed briskly with brandy. This had produced vesication over the nævus, and subsequently suppuration and sloughing. A linseed-meal poultice had been applied by the parents, with the result that an enormous sloughing cavity was produced, at the bottom of which about two square inches of the trapezius were exposed, the child suffering correspondingly from septic absorption. This case, he said, illustrated the need for active interference with these tumours. A similar amount of suppuration and sloughing among the tendons surrounding the wrist-joint could hardly fail to permanently incapacitate the hand. With the nævus in the patient at present under consideration, excision was first considered, this being the ideal treatment wherever possible. There was, however, one great drawback to this: so extensive an area of skin would have to be removed that it would be impossible to suture the incision—at any rate, without very great tension. A tense contracting scar upon the abdomen would, he pointed out, cause but little inconvenience, but upon the wrist, where there was only a limited amount of tissue, it would have acted as a constricting band producing permanent œdema of the hand. Electrolysis was a method which was admirable in many ways but it was extremely slow in its action, and, in some cases was practically ineffectual. He had decided, therefore, to employ the electro-cautery. This had been done several times, and the effect on the tumour was very satisfactory. The cautery employed was a fine platinum point heated to a moderately bright red heat; this was thrust into the tissue at intervals of about a quarter of an inch all round the margin of the nævus, and then the surface of the tumour was punctured all over, the punctures being about the same distance apart. A very distinct sensation could be felt by the operator when the dermis itself was perforated, the needle going on with a jerk, and so indicating that he had gone far enough. No hæmorrhage resulted as a rule, but occasionally, especially if the needle became over-heated, a slight amount of blood escaped. This was checked by a further application of the cautery, till the whole surface was dry. A dressing was then applied, consisting of a thin layer of wool painted over with Friar's balsam. By employing the cautery in this way, Mr. Edmunds said, only a very limited amount of the surface epithelium was destroyed, and when the dressing fell off after each application, the punctures were found soundly healed. The operation was repeated, the punctures now being made between the original ones, whose site was indicated by bluish white scars. In this way, by repeated applications of the electro-cautery, the nævus was being cured without any septic complications and without any excessive cicatrisation. The epithelium which had been destroyed at one operation was regenerated on the adjacent epithelium, and served in its turn as a source for fresh epithelium to replace that destroyed by the second operation. In this way, although the whole of the epithelium over the tumour was at one time or another destroyed, there was no great deficiency at any one time, and in consequence there resulted no ulceration or contraction. The scars produced by this method were, he remarked extremely good, being little inferior to those produced by electrolysis. In fact, the operation of electrolysis very frequently, he considered, was nothing more or less than a puncture with a fine cautery, the negative needle having an action which was practically that of a hot fire. The operation he had just employed has to be performed repeatedly until the whole nævus was cured, but the time and trouble spent were, he thought, amply compensated by the result obtained.

OPERATING THEATRES.

ST. PETER'S HOSPITAL.

CASE OF URETERO-LITHOTOMY.—Mr. SWINFORD EDWARDS operated on a man, æt. 28, who had been admitted for hæmaturia. The patient had never suffered any pain on micturition, nor was there any increased frequency in passing water. The patient stated that the discoloration of the urine was greater towards the end of the act of micturition. Taking this together with the absence of pain, Mr. Edwards thought that on cystoscopy he would find a vesical papilloma. Cystoscopy was carried out under an anæsthetic, when the right ureteric orifice was found to be protruding and everted, with œdematous folds of mucous membrane. The left ureteric orifice was normal. There was no other lesion in the bladder. The appearance of the right ureteral orifice, Mr. Edwards said, clearly pointed to a stone, probably impacted in the ureter, and which this canal was making every effort to get rid of. Operative interference had been postponed, not only to get the patient's consent, but also, if possible, to verify the diagnosis by radiography. The man was again brought up the following week, an X-ray photograph having in the meantime been taken, which showed a well-marked shadow deep in the pelvis on the right side, apparently at about the level of the upper part of the great sacro-sciatic notch. The operator made a six-inch incision on the right side in the abdominal parietes, as if he were about to ligature the common iliac. The peritoneum having been reached, this was carefully peeled off the posterior abdominal wall; a considerably dilated ureter was found to the under-surface of the serous membrane; this was isolated and followed down towards the bladder over the iliac vessels. The stone was carefully palpated for, first intra-abdominally, and secondly bimanually, one finger being in the rectum; but these means failed to locate it. Accordingly the dilated ureter was opened just above the level of the pelvic brim, and a probe passed downwards towards the bladder; a stone was struck about two inches from the aperture in the ureter. An endeavour was now made to express the calculus through the opening in the ureter, but it could not be manipulated higher up than one inch below the incision already made; a second incision was therefore made on to the stone, the left hand of the operator steadying it for this purpose. The calculus was extracted and was found to be black in colour, somewhat polished on one surface, and of the size of a long plum-stone. Both incisions into the ureter were now closed by Lembert's sutures, and after careful swabbing of the part of all bloodclot, a long rubber drain was inserted, one end being placed over the ureteric lesion and the other brought out through a separate opening made in the flank just above the iliac crest. The various layers of the abdominal wall were brought together by sutures. Mr. Edwards said that this case only instanced the fact that one could never be quite certain of a correct diagnosis by symptoms only, for here the symptoms had decidedly pointed to the presence of a vesical papilloma and the symptoms of stone were remarkable by their absence. From what was brought to light at the operation, one might have expected, he remarked, to have found not only hæmaturia, which certainly was present, but also attacks of renal colic and ureteral pain; combined with this one might have expected to have discovered a large and tender kidney, possibly also some increased frequency in micturition, and a deposition of crystals and some little pus in the urine; all the more might one have expected to have found some loin pain, as the effects of back pressure were markedly displayed in the dilated and thickened ureter. The absence of pain in this case he thought might be accounted for by the fact that the stone was roundish and smooth, instead of being of the spiculate variety. The obstruction of the passage of the calculus into the bladder was, he thought, probably caused by the narrowing of the ureter, where it passes obliquely through the bladder-wall. Mr. Edwards believed that this was quite the best method of approaching a stone when it is impacted in this position, or in any part of the ureter between the bladder and the iliac crest; for stones in the pelvis and in the upper part of the ureter, the ordinary lumbar incision was, of course, the one to employ. He remarked on the failure at first to locate the calculus by bimanual palpation, and he wondered for a moment if the shadow cast in the X-ray photograph might not have been caused by an enlarged lymphatic gland, which was found lying under the external iliac vein just below the brim of the pelvis. The fact of striking the stone with the probe gave him, he said, the certainty that it was there, and thereby assured the success of the second endeavour.

It is interesting to note that the patient made a very rapid recovery. The drainage-tube was taken out on the third day. No urine has escaped, and now, a week after the operation, the patient is practically convalescent.

TRANSACTIONS OF SOCIETIES.

EDINBURGH MEDICO-CHIRURGICAL SOCIETY.

Meeting held January 16th, 1907.

Dr. J. O. Affleck, President, in the Chair.

Dr. **Byrom Bramwell** showed a case of loss of the stereognostic sense. The patient was a man who had fallen and sustained a fracture of the base of the skull. This was followed by weakness of the right arm and right side of the face. Two months later he was admitted to hospital complaining of stammering and loss of power on the right side, the dynamometer reading being 30 in the right hand and 120 in the left. Tactile sensation was impaired all over the right half of the body. The condition was regarded as in part functional, and under treatment by isolation and suggestion, there was considerable improvement. The patient, however, returned to hospital after a few months with the same speech defect as before. There was also hemianæsthesia on the right side, deafness in the right ear, and loss of the sense of smell. The visual fields were not contracted. He was again healed by rest, isolation, and suggestion. He now showed weakness in the right side and partial anæsthesia. There was in addition complete loss of the stereognostic sense. The patient could feel touch and temperature, but could not distinguish the forms of common objects—a tumbler, a knife, keys, coins, &c.—placed in his right hand. On shaving the head a depression was found in the skull just behind the motor areas, and it was proposed to have the bone elevated with the object of seeing whether that would relieve the symptoms.

Dr. **Allan Jamieson** showed two improved appliances for dermatological therapeutics. One was called epicolloid; it had been prepared at his desire by dissolving pyroxylus in acetic ether. It presented certain practical advantages over flexile collodion, and could either be used as a protective, or as a basis for applying zinc oxide, salicylic acid, &c. The other was a specially thin and translucent form of adhesive plaster for covering cracks and abrasions.

Drs. **Bruce** and **Harvey Pirie** showed specimens of syphilitic meningo-myelitis, with photographs and microscopic demonstration.

Dr. **Chalmers Watson** gave a microscopic demonstration of the favourable effect of oatmeal on the thyroid gland of growing animals.

Mr. **Cotterill** showed an enormous tumour of the parotid.

Dr. **Dawson Turner** read a paper on the

HÆMO-RENAL SALT INDEX AS A TEST OF THE FUNCTIONAL EFFICIENCY OF THE KIDNEY,

a full abstract of which will be found on page 93.

Dr. **Burn Murdoch** read notes of some

CASES TREATED BY BIER'S METHOD.

Case 1 was that of a schoolboy who received an injury to the shin on January 18th; on the 20th, there was an acutely painful swelling of the bone with constitutional symptoms. The temperature was 102°, and the pulse 120. The symptoms pointed to acute osteitis, and an operation suggested itself; but Bier's treatment was adopted, with the result that the pain at once disappeared, and the temperature fell to normal by January 23rd. Case 2 was of a similar nature. Shortly after the receipt of the injury the tibia became acutely painful, and the temperature rose to 100°; next day it rose to 103°, and the congesting band was applied. The temperature fell to normal in a week, and all symptoms subsided. Case 3 was one of extremely obstinate ulceration of the leg, resembling what is known as Bazin's disease. The patient had been under treatment in private and in hospital for more than a year without being cured; under Bier's treatment the ulcers healed in ten days. As to the nature of the first and second cases, the speaker said that they clinically exactly resembled cases which, in the past, had been diagnosed and operated on as acute osteomyelitis by the surgeons called in in consultation. He warmly advocated Bier's method from the point of view of the general practitioner. The paper was discussed by Drs. Dickson and Flett, both of whom mentioned very successful cases healed in this way, and by Mr. Wallace, who said that, on the whole, he had been less fortunate. He doubted whether passive congestion could be of great use in osteomyelitis; probably, too, it was less successful in cases in which a suppurating focus had been incised than in cases in which this had not been done.

Dr. **James** read a note on the

NOTIFICATION OF INFECTIOUS DISEASES.

The infectivity of phthisis was relatively slight; notification was therefore undesirable on two grounds—(1) because it handicapped the patients in earning their livelihood, and (2) because it diverted the attention of the public and the profession from the true cause of the disease. He proposed to consider the notification of phthisis in relation to the notification of other diseases. The argument of those who favoured notification was that the organism was present in a great number—perhaps 40 or 60 per cent.—of healthy persons; as soon as the nutrition became lowered it started phthisis. By compulsory notification the foci of infection would be stamped out, and the disease exterminated. Dr. James, however, argued that the soil was as important a factor as the seed, and asked, Can you exterminate the soil? We had had compulsory notification of infectious disease for twenty years; let us see what it had done. He showed charts of the mortality from phthisis, typhoid, diphtheria, scarlet fever, and measles during a period of forty years, twenty years before, and twenty years since the enforcement of notification, and in these it was demonstrated that except in the case of scarlet fever the fall in mortality was no greater than in the case of phthisis, which had not been notifiable. The general improvement in all cases was ascribable to improved sanitation and not to notification, except in the one case, scarlet fever. Notification, therefore, had not met with the success expected. At present all the public were crying out for notification as a panacea, just as sixteen years ago they had run after the tuberculin treatment. He thought the profession ought to think the position out carefully and not give advice which would afterwards turn out to be wrong. What possibly could be expected from the results of notification, when we were as yet in the dark as to how infection arose, whether through milk, air, &c. The conditions under which people lived were far more important than the virulence of the organism; a person might take phthisis when not in contact with infection if his vitality was lowered.

Dr. James's paper was strongly criticised by Dr. Byrom Bramwell, and Dr. Carnhill, and supported by Dr. McVie, Dr. Hunter, and Dr. Webster.

The prize of £50 given annually by Sir John Craggs, M.V.O., to the London School of Tropical Medicine for presentation to the author of the most valuable contribution to tropical medicine during the year has just been awarded to Fleet-Surgeon Bassett-Smith.

THE LARYNGOLOGICAL SOCIETY OF LONDON.

MEETING HELD JANUARY 4TH, 1907.

The President, Dr. J. B. BALL, in the Chair.

THE following communications were made :—

Dr. WATSON WILLIAMS showed stereoscopic skiagrams of the nasal accessory sinuses.

Dr. ST. CLAIR THOMSON and Dr. HERBERT TILLEY exhibited specimens of cartilage and bone removed by means of Killian's sub-mucous resection operation for the correction of deviations of the septum.

A discussion followed on the relative merits of local and general anæsthesia for this operation. On this point opinions appeared to be divided.

Dr. JOBSON HORNE exhibited macroscopic preparations illustrating cystic disease of the larynx and a condition simulating cystoma.

Dr. W. H. KELSON showed a woman æt. 65, with a circumscribed tumour of the palate of about eight weeks' duration. There was a difference of opinion as to its nature, the diagnosis being a fibro-adenoma or an endothelioma. It was generally agreed that it should be removed.

Dr. KELSON also showed a patient with ulceration of the epiglottis and of the base of the tongue which was regarded as malignant disease and inoperable.

Mr. P. DE SANTI showed a case of tertiary syphilitic laryngitis for opinion as regards treatment.

Dr. A. LIEVEN recommended tracheotomy to keep the parts at rest ; if it were not done now it would have to be done later to overcome the contraction of the glottis. He advised injections of calomel, using 1 part of calomel in 10 of vasanol, a new preparation of paraffin which was the least irritating vehicle he knew. A very small dose should be given at first, as the patient might be intolerant of mercury.

The PRESIDENT showed a case of laryngeal disease presenting difficulties of diagnosis. Opinions were in favour of it being due to syphilis.

Mr. C. A. B. HORSFORD showed a patient with considerable enlargement of the cervical glands following removal of a tonsil. The diagnosis rested between primary chancre of the tonsil, malignant disease, and deep suppuration in the neck. It was advised that anti-syphilitic treatment should be used before incising the neck.

Dr. HORSFORD was asked to report to the Society the subsequent history of the case.

On behalf of Dr. G. C. Cathcart, Dr. JOBSON HORNE showed the specimen from a case of fibroma of the larynx present at the last meeting of the Society. When the patient was exhibited there was a general consensus of opinion that the tumour, which occupied the left arytenoid region, was a cystoma. It was subsequently found to be a solid tumour which had to be removed through an external incision.

GLASGOW EASTERN MEDICAL SOCIETY.

MEETING HELD WEDNESDAY, JANUARY 16TH, 1907.

The Vice-President, DR. JOHN PATRICK, in the Chair.

DR. GEORGE MCINTYRE read an interesting and instructive paper, on the

TREATMENT OF ECZEMA,

with special reference to the mode of external applications for the relief and cure of that distressing skin disease. It is a well-known fact that eczema is an inflammatory condition of the skin, with the usual exudations, which is responsible for the papules and vesicles that occur ; that when it assumes a pustular form that is due to the invasion of the pus-producing organisms. Then the exudation is apt to cake and form crusts, which are a barrier to successful treatment. Now Dr. McIntyre insists that the skin must be kept clear of those crusts. For this purpose they may be softened by vaseline freely applied and covered with gutta-percha tissue. Or oil may be used. If the eczema be in the acute stage, starch poultices may be applied, but there must be a layer of muslin between the poultice and the skin. The starch poultice may consist of boracic acid, 2 ounces, 1 to 4 drachms of starch, mixed with cold water, and then one pint of boiling water added. The whole should be included in a jacket of muslin half an inch thick. For oozing eczemas, clear lotions (that leave no deposit) may be used in the first instance, such as lotions of boracic acid, or black wash, sopped on for ten minutes at a time. Lotions with sediments may be employed in dry erythematous forms, and should be brased on for ten minutes at a time. A protective layer of powder is thus obtained, and the parts further protected by lint and a bandage.

Calamine lotion is very suitable for general use to which may be added a little carbolic acid, if there be much itching. In any case the skin has to be, cleansed daily by oil or other agent.

Ointments are useful after the acute stage. They should be spread thickly on the smooth side of lint, to prevent sticking.

To remove grease in cleansing, hot water may be used for several minutes (two). Lassar paste—starch 1, oxide of zinc 2, vaseline 2—is very suitable for leeting surfaces, and is more porous than ointments.

Dr. DAVID COOPER, who has had a very extensive experience of skin diseases, laid emphasis on the importance of rest in bed in obstinate cases, and stated that by that measure alone he had seen refractory skin diseases take a turn for the better. He praised starch poultices, and some of the older methods of treatment, such as zinc-gelatine paste. He summed up that the whole treatment might be put under three heads—(1) cleansing ; (2) soothing ; (3) stimulating, with a good general knowledge of internal medicine.

Dr. PETER BUCHANAN spoke of the value of giving alkalies and aperients internally, which Dr. MACLACHLAN also emphasised.

Dr. SERVICE extolled the value of cleansing the skin by gruel or oil.

Dr. ALEXANDER MUNRO spoke of the value of simply applying boiled bread and milk, which the illiterate understood how to prepare, and he referred to the value of a poultice of a boiled potato beaten up with buttermilk, which practically was an easily prepared starch poutice.

NORTH OF ENGLAND OBSTETRICAL AND GYNÆCOLOGICAL SOCIETY.

MEETING HELD AT MANCHESTER, JANUARY 18TH, 1907

Mr. R. FAVELL (Sheffield) in the Chair.

Dr. E. O. Croft (Leeds) was elected President, Dr J. H. Willett (Liverpool) Secretary, and Dr. W. K. Walls (Manchester) Treasurer for 1907.

Mr. FAVELL showed a large hypernephroma of the left kidney which occupied the pelvis and lower portion of the abdomen, and was successfully removed by the abdominal route.

Dr. J. B. HELLIER (Leeds) showed a fibroid polypus of the cervical canal which was of such a size that it completely filled the vagina, and was so irregular in form that it closely simulated a "cauliflower excrescence of the cervix."

Dr. A. J. WALLACE (Liverpool) showed a uterus removed for cancer of the cervix by the abdominal route, with extensive dissection of the pelvic glands and connective tissue. The obturator gland was shown to be much enlarged by secondary deposits, as were also glands dissected off the iliac vessels. Dr. Wallace regarded vaginal hysterectomy as merely palliative. He had done the extensive abdominal operation in nearly 20 cases, with a mortality of under 30 per cent. In fat subjects the operation was dangerous and prolonged, but in thin patients it did not appear to be attended by undue risk.

Dr. LLOYD ROBERTS (Manchester) showed a fibroid 13 inches in diameter and weighing over 32 lbs. It was removed from a multiparous widow 44 years of age who had been aware of its presence for 14 years. It finally produced pressure symptoms, menorrhagia, and metrorrhagia. The capsule was incised, and the growth enucleated as a preliminary to the removal of the uterus at the level of the internal os. Recovery was uneventful.

Dr. E. S. BISHOP (Manchester) showed a specimen illustrating the advantage of anterior vaginal hysterotomy for the removal of certain sub-mucous fibroids, also an example of ectopic gestation, in which the symptoms and history suggested gonorrhœal pyosalpinx rather than tubal pregnanacy.

CORRESPONDENCE.

FROM OUR SPECIAL CORRESPONDENTS ABROAD.

FRANCE.

Paris, Jan. 20th, 1907.

SLOW PULSE.

THE slow pulse, or malady of Stokes Adams, is an affection characterised by a decrease in the number of radial pulsations, and by accessory nervous troubles.

The slowness of the pulse in this affection differs from that observed in cerebral diseases (meningitis, cerebral hæmorrhage), after strong emotions or intense suffering, during the convalescence of diphtheria, typhoid fever, and other grave maladies, or in poisoning by digitalis or lead.

The disturbance of the cardiac system in the disease of Stokes Adams is very special, as the sphygmograph tracings taken simultaneously on the radial pulse and the jugular veins go to prove. The jugular pulsations are synchronous with the contraction of the auricles, while those of the radial artery are the consequence of the contractions of the ventricles. In permanent slow pulse two or three pulsations of the jugular veins go to one of the radial artery. The defect in the propagation of a certain number of contractions of the auricles to the ventricles is the cause of the slow pulse in this affection.

In the normal state, says Professor Josué, the propagation of the wave of contraction goes from muscular cell to muscular cell. The contraction of the ventricle follows that of the auricle, because the stimulation is transmitted by a small muscular band uniting the auricles to the ventricles. This band, described by His, extends from the posterior wall of the right auricle to the inter-ventricular septum. His and Graupner demonstrated that if this band was cut in the dog, the auricles and the ventricles contracted independently. It is precisely this phenomenon that is observed in permanent slow pulse. It may be mentioned that Schmoll found recently, in making an autopsy of two subjects who had suffered from permanent slow pulse, that these bands of His had been destroyed.

The nervous troubles never fail in the course of the disease of Stokes Adams. They consist in simple vertigo or attacks of violent cephalalgia. Sometimes fainting or epileptiform seizures are observed.

The duration of the malady is variable, and in general difficult to limit. The individual sometimes succumbs suddenly during an attack; at other times death is the consequence of asystole, which develops generally very insidiously.

The disease is more frequent in man, and at an advanced age. Arterial atheroma, traumatic or spontaneous lesions of the bulb or of the pneumogastric nerve, have been incriminated as causes of the affection.

The treatment should be both moral and therapeutic. The patient should avoid fatigue, emotions, or efforts. He should lead a life of absolute tranquillity, and avoid any cardiac or nervous excitement.

The regimen will consist essentially of milk and milk foods; very little meat should be allowed.

If the patient is suffering from sclerosis of the arteries, small doses of iodide of potassium will be prescribed (10 to 20 grains a day). Trinitrine is also very useful.

Solution of trinitrine	mm. xxx.
Water (1-100)	oz. x.

3 tablespoonfuls a day

Sometimes signs of renal insufficiency, with a decrease in the quantity of the urine, are observed. In such cases an absolutely milk diet should be prescribed to ward off the danger if possible.

Where the patient is threatened with a paroxysm, nitrite of amyl might be inhaled. Chauffard recommended for the same reasons the administration of atropine, which has the property of paralysing the intra-cardiac terminations of the pneumo-gastric nerve.

When the heart weakens, and asystole sets in, sulphate of spartein may be given, or injections of caffein or camphorated oil. Digitalis, says Professor Josué, is an absolute poison in cases of slow pulse, and consequently should never be given.

TREATMENT OF BOILS.

Boils, or furunculosis, are considered difficult to cure. The existence of a special diathesis was mentioned to explain the failure of therapeutic treatment. Be that as it may, one thing is certain—that furunculosis can be cured by purely local treatment. M. Gallois is accustomed for several years to treat such cases as follows, and always successfully:—

Metallic iodine	dr j.
Acetone	dr. iiss.
Absorbent cotton-wool.	
Glycerine	oz. vj.
Boric acid	dr. v.
Ordinary cotton	
Three bandages of muslin.	

He proceeds as follows:—

In case of furunculosis there exists a large boil under development and a lot of small ones forming satellites. He takes a match and surrounds its free extremity with a piece of cotton, and dips it into the iodacetone and touches each of the little boils, giving them the appearance of so many "beaufy spots." For the large boil, if it has not burst, he paints on the same solution; if it is open, he does not touch it with the bistoury. He never incises boils, and rarely an anthrax.

He then takes a piece of absorbent cotton, large enough to cover the whole region, and steeps it in a solution of boric acid or simply in boiled water, and wrings it out as much as possible He pours on it the solution of boric acid in glycerine until it is thoroughly wet with it, and applies it to the boils and covers it with ordinary cotton, and the whole is fixed with a bandage.

The dressing is renewed once a day, or twice if suppuration were abundant. After the first dressing the boil is observed to be less turgescent, while the surrounding skin is in a perfect condition, all the redness and the little pustulæ have disappeared.

To succeed in this treatment, M. Gallois insists that care and antiseptic precaution should be observed; that for this reason the medical attendant should apply the dressings himself, and not entrust them to the patient or his friends. A boil well dressed according to the above indications is never followed by others.

ALBUMINURIA.

Lactate of strontium	grs. iv.
Theobromin	grs. iv.
Tannin	grs. iv.
Phosphate of soda	grs. iv.
Oxalate of cerium	gr. j.

For one wafer. To be taken in the morning in an infusion of broom tops.

HAY FEVER.

Solution of adrenalin	mm. xx.
Cocaine	gr. ½.
Water	dr. iiss.

Steep a plug of cotton fixed on the end of a probe, and apply the solution to the mucous membrane of the nostrils.

GERMANY.

Berlin, Jan 20th. 1907.

At the Medizinische Gesellschaft Hr. Toby Cohn showed a young girl suffering from

Loss of Speech.

A week before she suddenly lost her speech, then regained it for a few hours, and afterwards lost it again. A physical examination showed only a specific exanthema.

She understood perfectly what was said. She carried out orders, recognised objects, knew how to use them, but could not name them. She could read, recognised pictures, and could name them. She could count, could name the days and weeks, but could not use them with any sense. She could not write spontaneously, but could copy correctly, though her writing from dictation was altogether wrong, and the same with repeating what had been said.

Neither the motor nor the speech centre could here be affected. By a process of exclusion it might be assumed that the seat of the disease must be the point of union between the acoustic and the motor centres, which would about correspond to the Island of Reil.

Specific treatment would probably restore the speech.

Hr. Letten showed two preparations of extreme

Syphilis of the Liver,

the one taken from an elderly woman, the other from a child. Both patients died of hæmaturia (melæna ?), the woman from a single attack, the child from a fifth. There were numerous gummata, which were also present in the spleen, which was enlarged. There were also in the liver large contracted portions.

The bleeding in cirrhosis of the liver, as the speaker had already pointed out, did not proceed from the stomach, but from the lowest segment of the œsophagus, the venous blood from which emptied into the portal vein. The varices, as the patients bled to death, were naturally found empty at the autopsies, but in both the erosion of large veins was distinctly visible.

Hr. Heubner spoke on

Orthsotatic Albuminuria.

He opened up the much discussed question whether the disease in which patients excreted albumen when in the upright position only, whilst during lying every trace of it vanished, was a particular form of nephritis, or whether it was a disease *sui generis*.

The first attempts to answer the question were first made by systematic measuring of blood pressure, and were made by Edel, who was followed by many others. It was shown that in orthostatic patients certain things would cause increase or diminution of blood pressure which in the healthy would produce the exactly opposite effect. Examination of the pulse, and also of the excretion of NaCl had also been made without bringing the question nearer to a solution.

The speaker had recently had the opportunity of making a *post-mortem* examination of a person the subject of typical ortholic albuminuria. The case was that of a child who had been scrofulous, and who for a year had passed much albumen in his urine, whilst up and about; but absolutely none whilst lying in bed. The child died of cerebral tumour after it had lain eight days in agony.

Microscopically, the kidneys evidenced no visible change; they were examined very carefully microscopically, but showed nothing distinctly abnormal. A slight fatty degeneration in places he attributed to the prolonged agony; a slight erosion of tissue in a single spot about 1 ccm. in circumference, and such as was often met with in older people with perfectly healthy kidneys, did not in his opinion affect the question at all.

Hr. Kraus would attribute a certain *role* to a poor constitution, but that alone could not give rise to the condition. At the last Insurance Congress—and albuminuria played a considerable part in life insurance—the question was ventilated whether a benign excretion of albumen could be distinguished from a malignant one. It was then considered that if when 1 grm. of lactate of lime was given in 24 hours to a man going about, he lost his albuminuria, then it was a benign and not a progressive form of the affection. The idea was that the blood in these people coagulated with difficulty, and that it was rendered more coagulable by the lactate of lime. He made this statement for what it was worth, he would not hold himself responsible for either the fact or the explanation. The subject must be gone into more closely; pathological anatomy alone could not elucidate it.

Hr. Senator did not think the kidneys shown to be normal, and saw in the slight changes they showed a basis for the belief.

When in the erect posture the blood pressure in the veins was greater, in the arteries less, than when lying down; stasis therefore occurred when the individual was standing up. If the stasis was increased experimentally by compression of the renal veins, the condition was brought about in the urine as regarded quantity, concentration, &c., as in orthostatic albuminuria, except that there was no albumen. There must be a factor therefore in the kidney itself. If the case was gone into more thoroughly it would be found that the individual suffering from orthostatic albuminuria had passed through some infectious illness, ground enough for the origination of a nephritis, the last faint echo of which was, in his opinion, the albuminuria in question. (Discussion adjourned).

A correspondent in a professional journal writes that the title of Professor was first allowed to Privatdocenten in Prussia in 1882, and that for the last ten years it has been rather freely distributed amongst physicians and surgeons. In the extra-Prussian States the conferring of the title on medical men who are not members of a medical faculty is still rare, especially in Saxony. Here, however, there has recently been opened up a path by which the coveted distinction may be gained, that is by qualifying at the Veterinary High Schools!

At the Freie Vereinigung der Chirurgen, Hr. Bosse related a case of

Peptic Ulcer of the Abdominal Wall.

A man, æt. 40 who had long suffered severely from gastric trouble was admitted into the Charité. There was dilatation of the stomach and a flat resistance at the pylorus. Gastro-enterostomy was performed, after which the stomach contracted and the acid secretion diminished. But the patient did not recover so as to be able to return to his work. After some months he returned with fresh stomach troubles, a rise of temperature, and infiltration of the abdominal parietes. An exploratory incision went into the abdominal cavity; the adhesions were but few. A piece of the infiltrated portion of abdominal wall was examined microscopically, and was found to consist of inflammatory tissue. During the next few days the tumour increased and the patient got lower. A fresh laparotomy was done, during which a large cavity was reached at the bottom of which was a gastric fistula. Excision was impracticable, and the patient became collapsed and died He had since found experimentally that injection of pancreatic juice into the tissues set up violent inflammation.

AUSTRIA.

Vienna, Jan. 20th. 1907.

Neoplasm of Cranium

Schrotter presented two cases at the meeting for "Innere Medicin" where the cranium was greatly enlarged, although the cerebrum did not appear to be increased. A prominent ridge in the bony structure could be observed to cease at the brow and parietal bones. Both ossa zigomatica and the bones of the nose were equally enlarged and broadened. The symptoms were pain in the head, most severe at night. No disturbance could be detected in the ocular apparatus, but the hearing was very defective in the perception of sound. He considered the morbid changes to be of a neoplastic character, which might either be sarcomatous or carcinomatous. What the primary cause was he would not offer an opinion, as no pressure on the cerebral nerves was present, nor any other symptom that would lead to such a conclusion.

Alexander thought that the defective hearing was due to atrophy of the acoustic nerves, and probably that of the Corti fibres.

Sternberg said there were six morbid conditions that might produce an enlargement of the cranium—viz., hydrocephalus, acromegaly, ostitis, deformans of Paget, hyperostosis of the cranium or the leontiasis ossea of Virchow, multiple neoplasms, and the tumour forming ostitis deformans of Recklinghausen, which often causes an enormous increase of the cranium. Sternberg was inclined to diagnose the primary cause of Schrötter's as being due to metastasis from some hidden neoplasm, or multiple in combination with hyperostosis and Recklinghausen's changes.

Schrötter thought that when no symptom of a hidden neoplasm could be distinguished, it was dangerous to diagnose a tumour. For acromegaly we would look for changes in the epiphyses of long bones, which were quite absent in this case. He could not see how it could be anything else but a neoplasm, either sarcomatous or carcinomatous.

Congenital Cardiac Anomaly.

Grossmann exhibited a young man, æt. 18, who was born with additional toes and fingers, retinitis pigmentosa, and a persistence of the ductus Botalli. The growth of the brain was inhibited after birth, the cranium not measuring more than 51 centimetres in circumference. On account of absence of cyanosis, a loud second sound, and a distal murmur beyond the aorta, stenosis of the pulmonary artery was diagnosed. Beyond the patent ductus Botalli and stenosis nothing more during life could be asserted.

Schmidt thought he could distinguish a systolic murmur over the pulmonary artery. From this he assumed there was a congenital malformation of the organ and a conus stenosis of the pulmonary artery.

Grossmann said the open ductus Botalli was in favour of an open pulmonary artery; and the radioscope rather tended to confirm this opinion.

Cardiac Defect.

Schwoner showed a case of congenital heart disease in a child 10 years of age, measuring 120 cm. in length, very slim and pale. The patient was cyanosed, and had drumstick fingers. The apex beat was found in the fifth intercostal space and in the mammary line, to which the cardiac dulness extended towards the left, while it reached the middle of the sternum to the right. Auscultation revealed a systolic murmur at the apex, and a diastolic sound over the manubrium sterni and left margin up to the second intercostal space, where rough systolic and diastolic murmurs were clearly distinguished, and, when felt with the finger, had a rough vibration. The second pulmonary sound was not accentuated. With the Röntgen rays the vessels on the left were seen to be enlarged, as well as the pulmonary artery corresponding to the ductus arteriosus Botalli. The pulse had nothing peculiar about it. The diagnosis arrived at was that this was an aneurysmal widening of the ductus Botalli in conjunction with pulmonary artery. The most peculiar feature in this case was the ease and comfort with which the child could run about and ascend stairs and hills without the slightest discomfort, not even complaining of palpitation or any other cardiac symptom.

CONTINENTAL HEALTH RESORTS.

WINTER ON THE RIVIERA.

[From Our Continental Correspondent.]

To gratify "stay-at-home" partisans, some journals have recently expatiated on the apparently higher average temperatures in London than at Nice. The latest December days exhibited a different array of figures, and from present health reports it is to be regretted that in consequence a smaller number than in previous winters came southwards prior to Christmas. After all is said and done, for the aged, the delicate, the convalescent, for "all requiring a mild tonic treatment, with a combination of mountain and sea-air, the proximity of pine woods, a temperate climate, and a non-irritating atmosphere," no more convenient to our British shores, and no more enjoyable localities can be found that those lying along the "Azure Coast" between Cannes and San Remo.

Nowadays, the far advanced invalids do not, as a rule, seek these resorts. Years ago it was different, and these Riviera districts were full of invalids. It is to-day amusing to read (as in "Harper's Hand-Book of 1868"):—"Since its annexation to France Nice has rapidly improved, not only in population, which now (1867) amounts to 55,000, but in everything which tends to promote comfort and pleasure. The principal hotels are Grand Hotel Chauvin, Hotel d'Angleterre, and Grand Hotel Brizzi, and the proprietors and servants speak English. The Chauvin is an immense establishment admirably conducted by its proprietor, Mr. Chauvin. The Angleterre has long maintained its position as one of the best houses in Europe. The Brizzi is finely managed by Mr. Brizzi, former proprietor of the Grande Bretagne. . . . The climate and waters of Nice are noted for the cure of the following complaints—Indigestion, Scrofula, Nervous Affections, Paralysis, Neuralgia, all Lymphatic Maladies, and diseases peculiar to females."

Of the hotels famous in 1867, the Chauvin and Brizzi are past and known no more; the Angleterre is yet prominent, but, like its neighbour, Hotel des Anglais, nowadays more German than English, and the Grande Bretagne enjoys chiefly an American patronage.

To-day Nice abounds with many and excellent hotels offering to their guests the most recent comforts and luxuries. As, on the celebrated Promenade des Anglais, the truly "Royal Hotel" of Mr. Ruhl, and on the now fashionable heights of Cimiez, Mr. Agid's most modern "Winter Palace," a genuine "thing of beauty," amidst artistic gardens, and with the highest degree of hygienic perfection.

FROM OUR SPECIAL CORRESPONDENTS AT HOME.

EDINBURGH.

UNIVERSITY OF EDINBURGH.—ANNUAL REPORT.

During 1906 the total number of matriculated students (including 463 women) has been 3,199, the highest attained for 13 years. The numbers are distributed through the various faculties as follows:—Arts, 1,012; Science, 292; Divinity, 56; Law, 311; Music, 28; and Medicine, 1,500, including 35 women. Of the medical students, 45 per cent. were Scottish, 20 per cent. English, 9 per cent. Irish, 5.5 per cent. Indian, 18 per cent. colonial, and about 2 per cent. from foreign countries. The number of women attending extra-academical lectures with a view to graduating in medicine was 71. The degrees in medicine granted during the year were:—M.B.C.M., 1; M.B.Ch.B., 186 including 17 women; M.D., 90, including 2 women; Ch.M., 1. The diploma in tropical medicine was conferred on 5, and the special certificate on 60 candidates. The report goes on to refer to the new buildings for engineering and natural philosophy, which were opened formally on October 16th; the former had already been in use for some months, and the latter will be ready for occupation next year. In transforming the old surgical hospital into the new premises it has been found possible to preserve the historic outer fabric almost without change. Although the Carnegie foundation has not manifestly increased the number of students, it is still noticeable that Carnegie students take out a larger number of classes than they would probably otherwise have done. Of those appointed to Carnegie post-graduate Fellowships and Scholarships, a considerable proportion are Edinburgh graduates. A lectureship in systematic and clinical gynæcology was instituted early in 1906, and Dr. A. H. Freeland Benbow was appointed lecturer. A lectureship on general and experimental psychology has also been founded. The following important personal changes fall to be recorded: Early in the year Dr. Henry Harvey Littlejohn was appointed Professor of Medical Jurisprudence in succession to Sir Henry D. Littlejohn. Dr. Norman Walker was appointed Lecturer on Diseases of the Skin, in room of Dr. Allan Jamieson, resigned; Dr. Logan Turner, Lecturer on Diseases of the Ear and Throat, in place of Dr. McKenzie Johnstone, resigned; and Dr. Melville Dunlop, Lecturer on Diseases of Children, in room of Dr. Burn Murdoch, resigned. The re-cataloguing of the library having been completed early in 1906, the remaining months of the year have been occupied by the cataloguing staff in the alphabetical arrangement of the entries and the insertion of cross references, work which will be completed in the course of 1907. The number of books dealt with in the general library is about 210,000; besides this, departmental libraries have been catalogued.

THE LATE DR. ALEXANDER PEDDIE.—There has just passed away from our midst, at the advanced age of 97, Dr. Alexander Peddie, who died in Edinburgh on January 19th. He was the father of the profession in Scotland, and probably in Great Britain.

GLASGOW.

DEATH OF THE PRINCIPAL OF GLASGOW UNIVERSITY.—By the recent death of Principal Story, the University of Glasgow has lost one of the most energetic and masterful Principals it has ever been its good fortune to possess. Principal Story was born at Roseneath, on the Firth of Clyde, where his father was minister for the long period of forty years. He succeeded his father, and his sterling gifts soon gained for him a distinguished position. He was called to be Professor of Ecclesiastical History some twenty years ago. On the death of Principal Caird, he was selected as his successor. During the eight years he has occupied this high office, he has infused new life into almost every department of the University. In Medicine, particularly, the new research laboratories in Physiology, in Pharmacology, and Public Health would be a sufficient monument to perpetuate his memory. But the whole field of Medicine has been brought up to date, and it is not difficult to predict that within a few years Glasgow University will attract students from all parts of the world, and be second to none. The very reverend gentleman occupied a foremost place in the General Assembly of the Established Church. He was cast in a heroic mould, fearless in speech, honest in conviction, and a steadfast man to the end.

BELFAST.

DOCTOR'S ACTION AGAINST GUARDIANS.—At the Clogher, Co. Tyrone, Quarter Sessions held last week, Dr. Warnock, of Clogher, sued the Guardians for twelve guineas for acting as *locum tenens* for Dr. Ross, medical officer of Clogher Workhouse. It appeared that Dr. Ross had been unwell, and had presented a medical certificate and asked for four weeks' leave, which the Guardians had granted, stipulating, however, that he should pay his own *locum tenens*. Dr. Ross got Dr. Warnock to act for him, and sent the bill to the guardians, who passed it for payment, and then rescinded it at their next meeting. Meantime the Local Government Board had sanctioned the payment, and informed the Guardians that they were bound to pay a substitute for their medical officer when he was absent on sick leave. The County Court Judge said that the Local Government Board letter was clear, and gave a decree for the full amount with costs, and a guinea for expenses.

DEATH OF A STUDENT FROM CEREBRO-SPINAL MENINGITIS.—Much regret is felt in medical circles at the sad death of a medical student in Belfast from cerebro-spinal meningitis. He was apparently in his usual health last week, and attended church on the morning of Sunday the 14th, but later in the day felt poorly and went to bed. He was seen in the afternoon by one of his teachers, who found him with a temperature of 106°, a slow pulse, and signs of cerebral irritation. He was taken to hospital, and died on Monday. Cerebro-spinal fluid, removed by lumbar puncture, on being examined, gave a pure culture of the typical diplococcus of cerebro-spinal meningitis. It is not known how the young man became infected, but he lodged in a part of the city from which several cases of the disease have been removed to the Purdysburn Fever Hospital.

TYRONE COUNTY HOSPITAL.—At a meeting held in Omagh last week, it was decided that the memorial to the late Major Burleigh Stuart should take the form of furnishing the County Hospital with electric light. The greater part of the money needed has already been subscribed.

TYPHOID AND MILK.—It is only a few months since we had a severe outbreak of typhoid in a suburb of Belfast, the source of which outbreak was clearly traced to the milk supply, a woman convalescent from typhoid having been employed as a milker in a dairy. Now comes the news that an outbreak at the other side of the city, happily so far confined to eight cases, has been traced to a contaminated source of supply near Larne. This will be an additional argument for the reformers on the City Council who wish to introduce proper methods of dairy inspection.

LETTERS TO THE EDITOR.

SPIROGRAPHS OR NASAL "BREATH PICTURES."

To the Editor of the MEDICAL PRESS AND CIRCULAR.

SIR,—The practice of testing nasal patency by breathing upon a prepared surface is by no means new, but its usefulness has been somewhat restricted by the want of a satisfactory material.

Slates, glass, and polished metals all have their shortcomings, but experiments have shown that vulcanite with a medium polish gives a very reliable and faithful image. By placing the plate horizontally on the upper lip, half an inch from the nostrils, and giving one short and steady expiration, a well-defined steam impression results which on evaporating affords reliable evidence of the actual and relative patency of the nostrils.

The image may be temporarily fixed, or rendered more conspicuous for demonstration purposes by lightly powdering it with calcined magnesia, or fine starch. Small sheets of vulcanite with a suitable surface and of a convenient size for the purpose are supplied by the Medical Supply Association, 228, Gray's Inn Road, London.—I am, Sir, yours truly,

WYATT WINGRAVE, M.D.

Central London Throat and Ear Hospital.

THE CASE OF EDALJI.

To the Editor of THE MEDICAL PRESS AND CIRCULAR.

SIR,—The efforts to prove the innocence of Edalji by seeking to establish that the crime for which he was convicted was an impossibility, owing to his error of refraction, reminds me of what happened when a notorious murderer was tried, convicted, and hanged at Newgate some years ago. Then it was that an optician wrote to the *Times* stating that at one time the murderer in question had "consulted" him for a defect of vision, and that he had found a high degree of hypermetrophic astigmatism. That being the case, the optician inferred, and the public, through the columns of the *Times*, were actually and solemnly informed that the moral obliquity which had led to the murder of two poor girls by means of strychnine was probably dependent upon the ocular defect. To argue that Edalji could not have maimed cattle or horses at night because of his myopic astigmatism, is just as wise, or—more plainly—just as absurd. The evil that is in a man is not controlled by his eyesight, nor could any defect of vision be, conversely, responsible for a criminal instinct. To raise, therefore, this question of the defect of vision in Edalji's case seems to me to be likely to weaken, rather than advance, the attempts made to establish his innocence. It is curious that

Edalji should never have made any complaint about his vision until some time after his conviction and imprisonment. This clearly goes to prove that the subject of his eyesight had not claimed the attention of his family. Moreover, it shows that, previously to being convicted, his vision was sufficiently satisfactory to Edalji himself. The argument, therefore, that he could not have seen to perpetrate that which he was convicted of doing must fall to the ground. Myopes who have never worn any correction for their defect have a wonderful way of adapting their vision to circumstances, and, of course, as is generally known, of improving it by the instinctive action of partially closing the lids. Again, it is curious that Sir A. Conan Doyle was the first to tell Edalji that he (Edalji) could not have committed the crime owing to the defect of his vision. Apparently nobody at the trial had ever thought of such a thing—not even Edalji himself.

Yours truly,
An Ophthalmic Surgeon.

London, W., January 18th, 1907.

To the Editor of The Medical Press and Circular.

Sir,—Will you allow me, a plain man and a medical practitioner, to make a suggestion in the case of Edalji, who has all along had the benefit of your able championship? From the Conan Doyle correspondence in the *Daily Telegraph*, I gather that Inspector Campbell was out with twenty men in the neighbourhood of the occurrence. It seems, further, that these men watched all the approaches to the field in which the pony was maimed on the night of August 17th, 1903. Then, perhaps most significant fact of all, Sergeant Robinson admitted that a certain number of men were specially watching Wyrley Vicarage. Under these circumstances, the police assert that Edalji evaded their patrols and committed an insane felony, as it were, under their noses. His father swears he did not leave the locked bedroom until seven next morning. The police have in the long run been utterly discredited. It is clearly proved that young Edalji had long been with them an object of distrust and suspicion, so much so that when the outrages took place, they were keeping a systematic watch round his house. Now, it has seemed to me from the first that if so gross a crime could be permitted in spite of their surrounding the field where it was committed, they stand convicted as incompetent blunderers. Under these circumstances few would have wondered had the defence put forward a theory of police connivance. But the lame defence of Edalji is one of the not least curious features of this strange drama.

I am, Sir, yours truly,
A Mere Country Practitioner.

OBITUARY.

EBENEZER TOLLER, M.R.C.S.

The late Mr. Ebenezer Toller, M.R.C.S., whose death took place at Scarborough on December 20th, 1906, was descended from a remarkable Bedfordshire family, his grandfather and three great uncles being between seven and eight feet in height each, and his four great aunts are described on an old engraving held in the family as the "Four Beauties of Bedfordshire." Mr. Toller elected to enter the medical profession, and entered at King's College Hospital, London. Mr. Toller was recognised as a hard-working student, and his name was several times mentioned in the honours lists. On leaving King's College he at once entered the lunacy branch of the profession, and became resident surgeon to the St. Andrew's Castle Private Asylum, Bury St. Edmunds; thence he went to the Middlesex County Asylum at Colney Hatch; and later was a successful candidate for the post of Medical Superintendent of St. Luke's Lunatic Hospital, London, and the ability shown by him in his management there enabled him successfully to apply for the similar post at the Gloucester County Asylum, which he held from 1863 to 1882. Mr. Toller was the pioneer in providing in lunatic asylums those entertainments which are now looked upon as a matter of course in every asylum. His musical ability prompted him, when a medical officer at Colney Hatch Asylum, to get up concerts for the patients. These and other forms of entertainment which he organised attracted great attention at the time, and were commented on in the *Times* and other papers, as well as receiving the recognition of the Commissioners in Lunacy as far back as March, 1862. At St. Luke's Hospital he was able to draw upon his many musical friends, and his concerts in that institution became an important musical "function." Mr. Toller was also a strong advocate of treating the insane in surroundings as homelike as possible, and deprecated strongly their being kept in large numbers in great buildings. These views he brought before the Association of Medical Officers of Asylums at the Royal College of Physicians in 1864, in a paper which was afterwards published with plans of cottage asylums.

JOHN FALCONER, M.R.C.S.

We regret to announce the death of Dr. John Falconer on the 6th inst. at Lasswade. Dr. Falconer was a son of the late Dr. John Falconer, who during a long period was a medical practitioner in Loanhead, and who was a fine type of the old country doctor. Dr. John Falconer studied at Edinburgh University, but took his M.R.C.S. degree in London. At the outbreak of the Crimean War he went to Smyrna as medical officer attached to the Turkish forces who garrisoned that city. He afterwards proceeded to China, and settled in Hangkow, where he resided for seventeen years. Thirty years ago he returned to this country, and settled at Lasswade, and latterly he had also a house in Edinburgh. He was a keen Freemason, was Past Master of the Celtic Lodge, and was a member of the Supreme Council of Grand Lodge. For a year past he has been in failing health, and the death three weeks ago of his only son doubtless accelerated the end.

SPECIAL ARTICLE.

BILL FOR THE INCORPORATION OF KING EDWARD'S HOSPITAL FUND FOR LONDON.

7 Edward VII.—Session 1907.

ARRANGEMENT OF SECTIONS

	Section.
Preamble	
Short title	1
Incorporation	2
Objects	3
President	4
Management	5
General Council and its duties	6
Transfer of existing property, and as to property generally, and trustees	7
Investments	8
Gifts subject to conditions	9
Indemnity	10
Costs of Act	11

A BILL

To Incorporate the President and Council of King Edward's Hospital Fund for London; to provide for the Management of the Fund; and for other purposes.

Preamble.—WHEREAS His Majesty then Prince of Wales did in the year 1897 invite public subscriptions (annual and otherwise) to a Fund now known as "King Edward's Hospital Fund for London" (hereinafter referred to as "the Fund") with the object of securing more efficient aid and support for Hospitals of London and of thus commemorating the sixtieth anniversary of the reign of Her late Majesty Queen Victoria.

AND WHEREAS the Fund was established and the same has been generously supported by public subscriptions donations and by legacies and otherwise.

AND WHEREAS His Royal Highness George Prince of Wales is now President of the Fund.

AND WHEREAS His Royal Highness has from time to time appointed certain persons to act as an Advisory Council and as Committees and in various other capacities and has with the advice and assistance of such Council and Committees administered the Fund.

AND WHEREAS it is expedient that for the proper establishment and administration of the Fund upon a permanent basis the President and Advisory Council should be incorporated and that provision should be made for the regulation and management of the Fund and with respect to present and future investments.

AND WHEREAS the purposes of this Act cannot be attained without the Authority of Parliament.

MAY IT THEREFORE PLEASE YOUR MAJESTY that it may be enacted and be it enacted by the King's Most Excellent Majesty by and with the advice and consent of the Lords Spiritual and Temporal and Commons in this present Parliament assembled and by the authority of the same as follows:—

1. *Short Title.*—THIS Act may be cited as King Edward's Hospital Fund for London Act 1907.

2. *Incorporation.*—FROM and after the passing of this Act His Royal Highness George Prince of Wales now President of the Fund and the present members of the said Advisory Council and the persons who hereafter shall be the President and the General Council respectively under this Act are hereby incorporated by the name of "King Edward's Hospital Fund for London" (in this Act referred to as "the Corporation") and by that name shall be a body corporate with perpetual succession and a common seal and with power without any further licence in mortmain to take purchase and hold lands and hereditaments and to sue and be sued, and with all other rights powers and privileges of a body corporate.

3. *Objects.*—THE objects of the Corporation are to secure from public beneficence by means of annual or other subscriptions of donations and bequests or otherwise funds and property which and all real and personal property now belonging to or held by any person or persons in trust for the Fund shall constitute a general fund of which either the capital and income thereof or any part of such capital or income as the President of the Corporation in his uncontrolled discretion may from time to time think fit shall be applied (*a*) in or towards the support or benefit of all or such one or more to the exclusion of the others of the Hospitals of London as the said President in his like discretion shall think fit and whether such application shall be for the general or any special purposes of any particular one or more of such Hospitals of London (*b*) in giving aid or assistance generally to all or any one or more of such Hospitals of London as the said President in his like discretion shall think fit and (*c*) generally in doing all such other things as are incidental or may be thought conducive to the attainment of the best interests of the Hospitals of London or any one or more of them or of the persons or any of them for whose benefit such Hospitals exist which the said President in his like discretion shall determine.

IN this Act the expression "the Sovereign" means His Majesty his heirs and successors Kings and Queens of the United Kingdom of Great Britain and Ireland and the expression "Hospitals of London" means and includes the following Institutions namely any present or future Hospital Convalescent Home Nursing Home or Nursing Institution Lying-in Institution Dispensary Medical Mission Society for the provision of Surgical or Medical Aid or Appliances and any Institution for the Rest Relief or Cure of Sick Persons as shall be situate within the County of the City of London or the Metropolitan Police District as existing at the passing of this Act or as the same may be hereafter extended or any Institution which being situate beyond such County or District shall afford Medical or Surgical treatment or Rest Relief or Cure to Patients all or some of whom are persons usually resident or carrying on their vocation in life within such County or District.

4. *President.*—HIS Royal Highness George Prince of Wales shall during the pleasure of the Sovereign be the President of the Corporation and every succeeding President shall be appointed by and hold office during the pleasure of the Sovereign.

5. *Management.*—THE direction control and management of the affairs and property of the Corporation and the application of all moneys property and income of the Corporation shall be vested in the President whose powers shall include the following that is to say (*a*) power to appoint and at pleasure remove the members of the General Council and of any other Councils and Committees hereinafter mentioned and Trustees Treasurers Secretaries Auditors and other officers and to award them or any of them salaries or remuneration (*b*) power to appoint and dissolve Councils and Committees other than the General Council and from time to time to delegate to any Council or Committee all or any of his powers of direction control or management as he may think fit (*c*) power to make vary and rescind bye-laws rules and regulations for the management and administration of the affairs and property of the Corporation and the procedure relating thereto, including the use of the corporate seal and the keeping of regular books and accounts (*d*) power to direct the mode of collection of moneys for the Corporation and the distribution and allocation of such moneys and of all property and income of the Corporation to or for the benefit of all or such one or more to the exclusion of the others of the Hospitals of London as he in his uncontrolled discretion shall think fit and generally to determine the manner in which such moneys property and income shall be dealt with and applied for the purposes of this Act and in furtherance of the objects of the Corporation (*e*) power to determine whether any institution proposed to be benefited is or is not within the limits of the objects of the Corporation as defined by this Act and (*f*) power generally to do or direct to be done all acts and things which in his discretion he may deem conducive to promoting and effecting the objects of the Corporation.

6. *General Council and its duties.*—THE General Council shall consist of such and so many persons as the President shall from time to time appoint. The duties of the General Council shall be to render to the President at his request such advice and assistance with respect to the affairs and property of the Corporation and the exercise of his powers in relation thereto as he shall from time to time require.

7. *Transfer of existing Property and as to Property generally and Trustees.*—ALL real and personal property now belonging to or held by any person or persons in trust for the Fund shall forthwith after the passing of this Act be assured transferred delivered and paid by such person or persons to or otherwise vested in or placed under the control of the Corporation or (if the President shall think fit) of the Trustees or Trustee to be appointed under this Act for the purposes of this Act but as to property given to the Fund upon any special trust or condition now affecting the same subject to such trust or condition.

ALL gifts by will or otherwise which if this Act had not been passed would have taken effect in favour of the Fund shall enure for the benefit of the Corporation.

ALL property of the Corporation for the time being not applied for the purposes thereof shall be and remain vested in the Corporation provided that any part or parts thereof may if the President shall think fit be from time to time vested in trustees to be appointed and removable by him and the Governor of the Bank of England may be appointed Sole Trustee for the purposes of this Act during the President's pleasure.

SUCH Trustees or Trustee shall dispose and deal with the property vested in them or him as the Corporation shall direct.

8. *Investments.*—ALL moneys and funds the property of the Corporation may (but as to gifts heretofore accepted on behalf of the Fund or which may hereafter be accepted by the Corporation with any special restriction as to investment subject to such restriction) be invested in the purchase or on the security of land of any tenure or in or upon such investments (whether authorised by law for the investment of trust funds or not) as the President may think fit and any investments may in like manner be varied from time to time or realised and the proceeds applied for the purposes of this Act. Land belonging to the Corporation may subject only to the consent of the President be sold leased or otherwise dealt with by the Corporation with the powers of an absolute owner. Any investments forming part of the Fund at the passing of this Act may be continued and the same and any investments heretofore made shall be deemed to have been made under the authority of this Act.

THE provisions of section 5 of the Mortmain Act 1891 as to the sale of land assured by Will to or for the benefit of a charitable use shall not apply to gifts by Will to the Corporation.

9. *Gifts subject to conditions.*—THE Corporation may accept gifts and endowments of real and personal estate either for special purposes of the Corporation or in aid of the general purposes thereof and upon such terms and conditions (not inconsistent with the objects of the Corporation) as may be agreed upon between the Corporation and the person bestowing such gifts and endowments.

10. *Indemnity.*—ALL persons hitherto acting in the management and application of the Fund shall be indemnified by virtue of this Act in respect of all acts and things done by them or any of them in the execution or intended execution in good faith of the trusts of the Fund as heretofore constituted.

11. *Costs of Act.*—THE costs charges and expenses preliminary and of and incidental to preparing and obtaining this Act shall be paid by the Corporation.

LABORATORY NOTES.

BENGER'S FOOD—ITS WIDER USES.

THERE is a saying that it takes fifteen years for a fact to become generally known to the medical profession, and though we are far from assenting to the proposition as stated in general terms, it is undoubtedly the case that to give a dog a good name imposes almost as many limitations as to give it a bad one. That is to say, that when a drug or preparation acquires a reputation under one set of circumstances, people are apt to overlook the fact that it may be useful in other very different ones. It is becoming a fashionable idea that one must go to a specialist for everything, and a general physician or surgeon finds if he gets a name for skill in some particular disease, the demand for his services gradually becomes confined to sufferers from that disease, the fact that he has a wide all-round knowledge of his profession being overlooked. So, too, with foods. Benger's Food has become a household word in connection with the feeding of infants and young children, and precisely for that reason the idea has grown up that it is "stuff for babies," and therefore not "stuff for men." Those who have used Benger's Food widely in various conditions do not need to be told that this is not so, that the range of "Benger" is coterminous with the range of enfeebled digestion, and that wherever the natural alimentary juices are lacking in strength, Benger's Food is able to reinforce them. The reason, of course, is that Benger's Food is, if one may use the term, a dynamic as well as a static food; it not only contains food elements, but ferments ready to act on them. Thus, besides an amylolytic ferment similar in action to the diastase of malt, it possesses also the power of digesting proteids, for to the food is added a proportion of pancreatic juice containing the natural proteolytic ferment, trypsin. Now the importance of a food such as Benger's is that it can be modified to suit any particular condition, and also used to modify the constituents of the milk with which it is prepared—in other words, Benger's Food is not only in itself a food, but it is a potential addition to milk whereby the defects of cow's milk as regards the human stomach can be removed, and its nutritive value reinforced to the extent which the medical attendant thinks desirable. In fact, Benger's Food can be prescribed with the accuracy of a tincture or extract, to meet all indications. All that is necessary is that the process of digestion (which begins when the food, after being rubbed up with cold milk, has boiling milk or milk and water added to it) shall be allowed to continue for the length of time necessary to complete the modification desired. When that point is reached, the food is quickly brought to the boil, the ferments are killed, and the reinforced and modified milk is ready. We lately took occasion to buy a tin of Benger at a shop, and after preparing it according to the directions for general purposes, made an analysis of the completed product. Thus we took a sample of milk from the Aylesbury Dairy Company, giving the following analysis:—

Specific gravity	1.0324	
Total solids	12.63	per cent.
Fat	3.78	,,
Mineral matter	0.78	,,

This milk we added to Benger's Food, according to directions on the tin—that is, after rubbing three-quarters of an ounce of the food into a paste with two fluid ounces of cold milk—we gradually added ten fluid ounces of boiling milk, stirring carefully the while. The whole was allowed to stand for fifteen minutes and then raised to the boil. The analysis was then proceeded with, and the following result obtained:—

Total solids	17.98	per cent.
Proteids	4.87	,,
Fat	3.90	,,
Carbohydrates	8.37	,,
Mineral matter	0.84	,,

From this it will be seen that a substantial addition was made to the total solids, especially as regards the carbohydrates, most of which, owing to the action of the amylolytic ferment, appeared in soluble form.

It is, however, important to remember that the directions on the tins are intended to guide unscientific people. A medical man in using Benger's Food can take advantage of the circumstances to give his patient any proportion of any particular ingredient he may desire, and that in almost any stage of digestion deemed suitable. For instance, if he desires a food poor in fat, he may prescribe Benger's Food either with milk and water or with skimmed milk, whilst if more fat than normal is necessary, a teaspoonful or more of cream may be added to the completed product. In one particular, however, Benger is of unexceptionable utility, namely, in being able to modify the proteids of milk. A short treatment with Benger's Food without converting much of the casein profoundly modifies it, so that it will no longer curdle in large masses. A more extended treatment will bring part of the casein into soluble forms, albumose and peptone, whilst by prolonged digestion it can be wholly converted.

In the preparation, however, of all modifications of milk and Benger's Food, it is necessary to bear in mind that in order to attain the temperature at which the ferments act best, ten ounces of boiling fluid—milk, milk and water, or what not—must be added to the two ounces of cold milk and food which have been rubbed up into a paste. It has been found by careful experiment that the resultant mixture attains a uniform temperature of about 158° F., and cools on standing—while the digestive process is going on—to about 125° F., and that it is between these points of the thermometer that the ferments act most vigorously. If larger or smaller quantities of fluid are used, temperatures unfavourable to ferment action are created.

With so polyvalent a food as Benger, with a food capable of modifying and being modified so profoundly, there is hardly a condition of immaturity or disturbance or disease of the stomach and digestive organs that cannot be catered for by prescription. In old age and in convalescence, no less than in infancy and illness, Benger's Food prepared with milk may be used to meet the particular circumstances of the case. But it is well that medical men who are in the habit of using the preparation should be acquainted with the modifications and modulations of which it is capable, and of the means by which they may be brought about.

REVIEWS OF BOOKS.

WHITING'S AIDS TO MEDICAL DIAGNOSIS. (*a*)

To compress within the limits of some 150 pages an account of medical diagnostics is by no means an easy task; yet the author of the volume before us has carried it out in a manner creditable to himself and pleasing to the reviewer. Dr. Whiting's method of treating his subject is "to start with the leading symptom or symptoms, and, after arranging the diseases presenting these symptoms in groups, to ultimately differentiate the members of each group as clinical entities." After an introductory chapter on the clinical investigation of medical cases, the writer goes on to deal with diseases of the various systems in a series of eight chapters. These are from his own pen, except that on infectious diseases, which has been ably written by Dr. Herbert Cuff.

Of course, in a small book such as this, it is easy enough to find defects. Many facts are wanting which might have been supplied had space allowed. What has been given, however, is correct, and that is the most important point in a book which will, we feel sure, be used by hundreds of senior students preparing for their final examination. Certainly the student who uses this book will find it a safe guide, and of inestimable value in mastering the essentials of medical diagnosis. Although its value largely depends on the smallness of its compass, we cannot but feel that its usefulness would be greatly extended were its size increased. With another hundred pages or so added we venture to predict that this "aid" would be the pocket companion of the general practitioner. As it stands, however, we can only say that we can confidently recommend it by reason of its accuracy of statement, its perspicuity of style, and its judicious arrangement of the subject matter. The publishers are to be congratulated on adding to their really valuable "Aids" series a volume so admirably put together and so well adapted for students' use.

WILLIAMS ON MINOR MALADIES. (*b*)

DR. LEONARD WILLIAMS has rendered a great service to the profession by the production of this handy and practical guide. The ordinary text-books deal very fully with all the serious diseases, but leave untouched the minor maladies of every-day occurrence—which are the cause of so much of the avoidable misery of life. The book before us fills in this lacuna in medical literature, for it treats very fully and adequately of colds, indigestion, headaches, goutiness, together with change of air and the problems of general health. All the statements are clear and explicit; there is no unnecessary verbiage, and many most useful prescriptions are given in full. We regard the book as of great value to the general practitioner, and to the young beginner in particular, and we cordially recommend it to the profession.

SUBMUCOUS EXCISION OF DEVIATIONS AND SPURS OF THE NASAL SEPTUM. (*a*)

DEVIATIONS of the nasal septum whenever they occur are very distressing, and frequently lead to mouth breathing and other unpleasant consequences. Mr. St. Clair Thompson has described very clearly a simple and somewhat ingenious method of operation for relieving this abnormal condition of nasal septum. Anyone contemplating operating on such a case would do well to carefully peruse beforehand this paper, which could be read in a few minutes, as it gives very clear instructions as regards remedying this malformation by operation, and several useful plates are given, with the histories of several cases.

NEW BOOKS AND NEW EDITIONS.

- BAILLIERE, TINDALL AND COX (London).
  - Lessons on Massage. By Margaret D. Palmer. Third Edition. Pp. 272. Price 7s. 6d. net.
  - Surgery of the Rectum. By Fred. C. Wallis, B.A., M.D., F.R.C.S. Illustrated. Pp. 168. Price 6s. net.
  - Clinical Lectures on Enlargement of the Prostate. By P. J. Freyer, M.A., M.D., M.Ch. Third Edition. Illustrated. Pp. 154. Price 6s. net.
  - War with Disease. By Frederick F. Maccabe, M.B. Second Edition. Pp. 125. Price 1s. net.
- CASSELL AND CO., LIMITED (London).
  - Tumours, Innocent and Malignant. By J. Bland Sutton, F.R.C.S. Fourth Edition. Illustrated. Pp. 675. Price 21s. net.
- CAXTON PUBLISHING CO., THE (London).
  - The Nursling: The Feeding and Hygiene of Infants. By Pierre Budin. Authorised Translation by Wm. J. Maloney, M.B., Ch.B. Illustrated. Pp. 199. Price 21s. net.
- CHURCHILL, J. AND A. (London).
  - Year-Book of Pharmacy. From July 1, 1905, to June 30, 1906. Edited by J. C. Braithwaite. Pp. 350.
- GRIFFIN, C., AND CO., LIMITED (London).
  - Practical Sanitation: A Handbook for Sanitary Inspectors and Others Interested in Sanitation. By George Reid, M.D., D.P.H., with Appendix on Sanitary Law, by Herbert Manley, M.A., M.B., D.P.H. Thirteenth Edition, revised. Illustrated. Pp. 352. Price 6s.
- THE HEALTH RESORTS BUREAU (London).
  - French Law and Customs for the Anglo-Saxon. By Arthur S. Browne. Second Edition. Revised and enlarged. Pp. 75. Price 2s. 6d. net.
- LIPPINCOTT, J. B., AND CO. (London).
  - International Clinics: A Quarterly. By A. O. J. Kelly, A.M., M.D. Vols. 2 and 3. Sixteenth Series, 1906. Pp. 302 each.
  - Pediatrics: The Hygienic and Medical Treatment of Children. By T. M. Rotch, M.D. Fifth Edition. Rearranged and Rewritten. Illustrated. Pp. 1,060. Price 25s. net.
- LONGMANS, GREEN AND CO. (London).
  - Sanitary Engineering with Respect to Water Supply and Sewage Disposal. By L. Francis Vernon-Harcourt, M.A., M.I.C.E. Illustrated. Pp. 419. Price 14s. net.
- MACMILLAN AND CO., LIMITED (London).
  - Anæsthetics and their Administration. By Frederic W. Hewitt, M.V.O., M.A., M.D. Third Edition, Illustrated. Pp. 627. Price 15s. net.
- METHUEN AND CO. (London).
  - The Control of Scourge; or How Cancer is Curable. By Charles P. Childe, B.A., F.R.C.S. Pp. 299. Price 7s. 6d. net.
- MURRAY, JOHN (London).
  - Recent Progress in the Study of Variation, Heredity, and Evolution. By Robert Heath Lock, M.A. Pp. 299. Price 7s. 6d. net.
- PENTLAND, YOUNG J. (Edinburgh).
  - The Edinburgh Medical Journal. Edited by Alexis Thomson, M.D., etc., and Harvey Littlejohn, M.B., etc. New Series. Vol. XX. Pp. 575.
- SAUNDERS, W. B., AND CO. (London).
  - The Technic of Operations upon the Intestines and Stomach. By Alfred H. Gould, M.D., Boston. Illustrated. Pp. 302. Price 21s. net.
  - Prevalent Diseases of the Eye. By Samuel Theobald, M.D. Pp. 551. Price 19s. net.
  - A Manual of Normal Histology and Organography. By Charles Hill, Ph.D., M.D. Pp. 463. Price 10s. net.
  - A Text Book of Obstetrics. By B. C. Hirst, M.D. Fifth Edition. Revised and enlarged. Pp. 915. Price 21s. net.
  - A Text Book of Pathology. By Alfred Stengel, M.D. Fifth Edition revised. Pp. 979. Price 21s. net.
  - Surgery: Its Principles and Practice. By various Authors. Edited by W. W. Keen, M.D. Vol. 1. Illustrated. Pp. 983. price 30s. net.
- SMITH, ELDER AND CO. (London).
  - Climatotheraphy and Balneotherapy. By Sir Hermann Weber, M.D., F.R.C.P., and F. Parkes Weber, M.D., F.R.C.P. Pp. 833. Price 15s. net.
- YEAR BOOK PUBLISHERS, THE (Chicago).
  - The Practical Medicine Series. Edited by Gustavus P. Head, M.D. 9 Vols.

(*a*) "Aids to Medical Diagnosis." By Arthur Whiting, M.D., M.R.C.P., Physician to the Tottenham Hospital and Assistant Physician to the Mount Vernon Hospital for Consumption and Diseases of the Chest, &c. Pp. x., 152. Fcap, 8vo, price 2s. 6d. London Bailliere, Tindall and Cox. 1907.

(*b*) "Minor Maladies and their Treatment." By Leonard B. Williams, M.D., C.M., M.R.C.P.Lond., Physician to the French Hospital in London; Assistant Physician, Metropolitan Hospital. Pp. 394. London: Bailliere, Tindall and Cox. 1907. Price, 5s. net.

(*a*) "Submucous Excision of Deviations and Spurs of the Nasal Septum." With a report of the first thirty operations. By St. Clair Thomson, M.D., F.R.C.P., F.R.C.S., Physician for Diseases of the Throat in King's College Hospital; Surgeon for Diseases of the Nose, Throat, and Ear, in the Seamen's Hospital, Greenwich. Pp. 48. London: Cassell and Company, Limited. Price 1s. net. 1906.

WEEKLY SUMMARY OF MEDICAL LITERATURE, ENGLISH AND FOREIGN.

Specially compiled for THE MEDICAL PRESS AND CIRCULAR.

RECENT PATHOLOGICAL LITERATURE.

Infectivity of Malignant Diseases.—Gaylord (*British Medical Journal*, Dec. 1st, 1906) publishes two cases highly suggestive of the infectivity of malignant disease. He refers to similar observations by Hanau on carcinoma in rats, by Borrel and by Michaelis on carcinoma in mice, by Cooper and by Loeb on carcinoma in cattle, and by Pick on carcinoma of the thyroid in trout. One of Gaylord's cases is the direct sequel to the case recorded by Loeb in 1904. Loeb, in the years 1901 and 1902, had observed in rats three cases of "cystic sarcoma" which was shown to be capable of transplantation. Some three years later, in a rat confined in one of the cages made use of in the transplantation experiments, a tumour exactly similar in structure appeared. This form of tumour is apparently very rare, since Gaylord has been unable to find any record of such a tumour elsewhere. In the other rats in the same cage sarcomata also developed, though somewhat different in type. The second case is more striking still. In one particular cage in the establishment of a mouse breeder, no less than sixty tumours have been discovered in the course of three years. The tumours all occurred in females, and were identical in type—adeno-carcinomata of the breast. In no other cage in the establishment did any tumours occur, although there were constantly several hundred mice in captivity. That the occurrence of the tumours was not due to any hereditary cause is established by the fact that an entire change of stock made no permanent difference. Gaylord concludes that his observations, taken with those previously published, are sufficient to justify a belief in the occasional contagiousness of sarcoma and carcinoma. R.

Bacteriology of Rheumatic Fever.—Beattie (*British Medical Journal*, December 22nd, 1906) defends the position of the organism described by himself and Poynton (*micrococcus rheumaticus*) against hostile criticism. (1) It has been objected that the organism is not causal, but that infection by it is only terminal. Against this is the fact that cultures from the blood, taken immediately after death, are negative, cultures of the organism being got only from limited areas of the synovial membranes. (2) It has been objected that the organism is merely an attenuated *streptococcus pyogenes*. Beattie details many cultural and inoculation experiments performed with the two organisms, showing many marked differences. *Streptococcus*, for example, produced joint lesions—all definitely purulent—in 18 per cent. of the cases, and endocarditis (of an ulcerative nature) in 2 per cent.; on the other hand, *m. rheumaticus* produced joint lesions, always non-purulent, in 60 per cent., and endocarditis in 33 per cent. (3) The author shows that the organism is usually absent from the blood and joint effusions in simple cases, though in severe cases it may be found. R.

Experimental Arterio-Sclerosis. — Klotz (*British Medical Journal*, December 22nd, 1906), in the course of a general discussion of the pathology of arterio-sclerosis, describes the results of certain experiments in the artificial production of that condition. He concludes:—(1) The effect of the high-pressure drugs (adrenalin, digitalis, barium chloride) on the arteries is a degenerative one. (2) The muscle cells of the media are first attacked, the elastic fibres being involved later. (3) The change is a fatty degeneration, accompanied by calcareous deposits. (4) Occasionally the intima shows proliferative changes. (5) The effect of adrenalin is not abolished if the blood pressure be lowered by nitro-glycerin. (6) Aneurisms are produced as a result of the destruction of the media. (7) Diphtheria toxins act on the arteries in a similar way to adrenalin. (8) Typhoid and streptococcal infections produce little destruction of tissue cells, but tend to stimulate cell proliferation of the intima and of the inner layer of the media. R.

Rarity of Cancer in Central Africa.—Hearsey (*British Medical Journal*, Dec. 1, 1906) comments on the extreme rarity of cancer among the aborigines of British Central Africa. Although innocent tumours such as lipoma and fibroma are fairly common, only a few cases of malignant disease have been noticed. No case of cancer of the breast has yet been discovered. Hearsey suggests that the absence of epithelioma of the mouth may be due to the fact that the natives are not subject to irritation either by jagged teeth or by hot pipes. Again, as regards the breast, it is made to perform its physiological function of suckling, and is therefore not so subject to pathological processes. R.

Degenerations of Fibroids of the Uterus.—Noble (*Journal of Obstetrics and Gynæcology*, November, 1906) discusses at considerable length the various degenerations to which fibroid tumours of the uterus are subject. He collates with his own figures those of Martin, Watt-Keen, McDonald, Lauwers, and other observers, so that he is able to pass in review some 2,274 cases. In 95 of these, *i.e.* 3.9 per cent., malignant degenerations or complications were present; more than one-third of the malignant cases were sarcoma, most of the remainder being cancer of the body. In 119 cases (4.7 per cent.) there was necrosis, of which the precise nature is not stated. Cystic degeneration was present in 58, or 2.5 per cent., of the cases, myxomatous degeneration in 89, or 3.4 per cent., hyaline degeneration in 80, or 3.26 per cent., fatty degeneration in 7, or .3 per cent., and calcareous infiltration in 47, or 1.95 per cent. In only 8 of the cases is there mention of endometritis. By adding together the cases of malignancy and other dangerous complications, the writer finds that in 275 cases of the series, or 12 per cent., conditions were present which, apart from operation, would prove fatal. In 14 per cent. of his own cases a fatal result was, he believes, inevitable were it not for operation. In view of the more frequent association of cancer of the body than of cancer of the cervix with fibroids, Noble is persuaded that the presence of fibroids is a causal factor in the production of cancer of the body. The main conclusion arrived at by the author is that fibro-myoma of the uterus is a more serious disease than is generally recognised, and that no fibro-myoma which is causing symptoms should be allowed to remain. R.

The Effect of Lime Salts in Pancreatic Digestion.—Delezenne (*British Medical Journal*, December 22nd, 1906) relates that pancreatic juice obtained in an inactive form acquires a powerful proteolytic activity when incubated for some hours with a soluble calcium salt. Pancreatic juice prepared in this way dissolves cubes of albumin as rapidly as if mixed with enterokinase. This action of calcium must be regarded as peculiar to itself, since the salts of other metals of the same series have no such effect. R.

Movements of the Uterus.—Cushny (*Journal of Physiology*, December 29th, 1906) describes the result of investigations into the mechanism of movements of the uterus. His experiments were carried out on rabbits, cats, and bitches. The movements, both longitudinal and circular, were recorded by an ingenious attachment of levers to the horns of the uterus. Connection with the central nervous system was destroyed, and Cushny believes that movements of the organ can take place independently of the central nervous system. (1) In the virgin uterus no spontaneous movements were observed, whereas in animals in heat and after pregnancy spontaneous movements were generally present. The spontaneous movements of the longitudinal fibres were slow, rhythmical contractions, resembling the pendulum movements of the intestine. The period between successive movements varied from fifteen seconds to twelve minutes. (2) In addition to the contraction of the longitudinal muscle fibres, movements were caused by the contraction of the fibres of the broad ligament, throwing the uterus into a spiral or curved form. (3) The movements of the circular fibres were very similar to those of the longitudinal, but they did not occur simultaneously. (4) Mechanical or electrical stimulation of the uterus caused a powerful contraction, whether the organ were in a state of rest or undergoing spontaneous contraction. The virgin uterus was always less irritable than the pregnant or parous uterus. (5) Stimulation of the hypogastric nerve generally induced powerful contraction of the whole organ in the rabbit, while in the cat the effect varied with the condition of the uterus. Thus, the virgin uterus was inhibited, whereas the pregnant or parous uterus contracted with vigour. (6) The general result of anæmia was to cause an increased tone. (7) The effects of various drugs were tried. A first injection of nicotin caused powerful contractions, but further injections showed diminishing effects. Pilocarpin increased the rate and strength of contractions. Atropin had no effect, except that it antagonised pilocarpin in cases where the latter had been previously administered. The effects of adrenalin were identical with those of hypogastric stimulation. Quinine produced marked contractions. Aloin had a similar effect. Alcohol produced no effect, and ether and chloroform only very slight relaxation. Ergot caused prolonging of the contractions, but no acceleration. R.

Effects of Adrenalin Injection.—Elliott and Durham (*Journal of Physiology*, October 29th, 1906) report the results of a series of experiments on cats by the injection of adrenalin. They conclude:—(1) In no case was there any evidence of the production of any antibody to adrenalin. It is possible that this result may not be applicable to other animals. (2) The muscles of the circulatory system were unaltered. (3) The suprarenal glands were somewhat enlarged. (4) The liver and kidneys showed obvious signs of poisoning. Polyuria with sugar followed each injection. The liver showed shrinkage, with fatty degeneration of the cells. The kidneys showed enlargement, with fatty degeneration of the tubular epithelium. R.

The Pancreas in Cirrhosis of the Liver.—Laudo (*Zeitsch. für Heilk.*, Bd. 27, H. i.) has examined the pancreas in twenty-three cases of typical liver cirrhosis, and in all cases found a more or less abundant overgrowth of connective tissue, which was sometimes distributed intra-lobularly, but more often was interlobular. The head and the tail of the pancreas were always equally affected, and in pigmentary cirrhosis of the liver a deposit of pigment was found also in the pancreas. The cell-islets of Langerhaus showed change in many cases, but in no case as marked as is to be found in diabetics. The form of liver cirrhosis, whether atrophic or hypertrophic, did not seem to lead to any variation in the pancreatic condition, which was apparently almost entirely to be ascribed to the venous engorgement following portal obstruction. M.

The Position of the Heart in Pericardial Effusions.—Schaposchnikoff (*Rev. de Med.*, 1905, p. 789) adds to his earlier observations on this subject the record of twenty-six more cases of pericarditis that he has studied. He concludes that the heart does not sink in pericardial effusions, as, according to Skoda, it is bound to do owing to its weight, but that, on the contrary, it is raised up and floats on the top of the effusion. The position occupied is of great importance from the point of view of paracentesis, and the author is inclined to advise puncture to the right of the sternum. M.

The Proteolytic Ferment of Leucocytes.—Eppenstein (*Münch. Med. Woch.*, 1906, No. 45) points out that already a chemical distinction between lymphocytes and polynuclear leucocytes has been made by many writers, in that the polynuclear cells and also myelocytes are capable of peptonising gelatin. The proteolytic ferment of these leucocytes works best in a slightly alkaline medium, and at a temperature of 55 deg. C. At 70 deg. C. the action becomes weakened, and at 75 deg. C. it is completely lost. Blood plasma and serum have a restraining influence on the ferment, and lately, by the chloroform method of Delezenne, an anti-proteolytic ferment has actually been isolated. In some cases of myelæmia this last-named ferment persisted even in the serum obtained ten hours *post mortem*, but the ferment was invariably greatly retarded by a temperature of 60 deg. C. M.

Ehrlich's Diazo Reaction in Phthisis.—Weisz (*Weiner Klin. Woch.*, 1906, No. 44) has systematically carried out the Diazo test on the urine of 257 patients suffering from pulmonary tuberculosis. The longest duration under observation was seven months, and the shortest one month. As a result of these observations he states that a positive reaction may be regarded as a serious symptom, and that the seriousness is emphasised by a persistence of the phenomenon. Often a positive reaction can be obtained after tuberculin injections. The urine is the only secretion which gives the reaction, and it is only found in fairly concentrated urines. M.

Undulant Fever in South Africa.—Dr. Strachan contributes a paper on the occurrence of Malta fever in South Africa to the *South African Medical Record*, December 10th, 1906, p. 345. He points out that a few previous writers have urged that the disease is prevalent in South Africa, but that it has not yet been generally recognised, and that most cases are still diagnosed as enteric fever. Since his own attention was attracted to the subject, he has met with numerous cases that were clinically undulant fever, and states that during the last four years 138 cases of this fever have occurred in his practice, while during the same time he only met with 30 cases of enteric fever. His diagnosis was based both on clinical symptoms and on the serum reaction with typhoid and Malta fever organisms respectively. As far as the latter test was concerned, out of 34 sera tested in dilutions up to 1 in 50, 25 gave a positive reaction with the micrococcus melitensis, 3 with the bacillus of Eberth, while 5 were negative with both. In one case that presented cerebral symptoms, the micrococcus was isolated at the autopsy from the brain. The complications of the disease and the mode of transmission are discussed, and the conclusion is derived from an examination of the milk that goats are most probably the culprits in the latter respect. The most common complication was lumbago, which occurred in 63 per cent. of cases. M.

Agglutination in Pulmonary Tuberculosis.—Jessen has made 122 observations of the agglutinative properties of the blood serum in 86 cases of pulmonary tuberculosis (*Brauers' Beitrage zur Klinik der Tuberk.*, Bd. vi., Heft ii.). In most cases which the author treated in Davos at a height above sea level of 1,500 metres, he found that without any specific treatment the agglutinative properties were increased. Those treated with tuberculin did not react a higher grade than the untreated cases. Clinical improvement was noted in most cases who presented an increase of agglutinative power, while the cases that ran an unfavourable course showed poor agglutinative re-action. On this account some value, at most slight, as a prognostic sign can be placed on this property. A reaction in a dilution of one in twenty-five can alone be regarded as positive, and reaction in slighter dilutions is absolutely valueless from a diagnostic point of view. M.

MEDICAL NEWS.

British Gynæcological Society.

AT the annual meeting of this society, held on Thursday, January 10, 1907, the following officers and council were elected for the current year:—

Hon. President.—R. Barnes, M.D., F.R.C.P., F.R.C.S. (Eastbourne).

President.—*W. Dunnett Spanton, F.R.C.S. (Hanley).

Vice-Presidents.—T. Gelston Atkins, B.A., M.D., M.Ch. (Cork); William Duncan, M.D., F.R.C.P., F.R.C.S. (London); Bedford Fenwick, M.D., M.R.C.P. (London); *Clement Godson, M.D., M.R.C.P. (London); H. Jellett, M.D., F.R.C.P.I. (Dublin); *J. Furneaux Jordan, M.B., F.R.C.S. (Birmingham); R. P. Ranken Lyle, B.A., M.D., B.Ch. (Newcastle-on-Tyne); J. J. Macan, M.A., M.D. (London); *H. Macnaughton-Jones, M.D., M.Ch., M.A.O., F.R.C.S.I. and Edin. (London); W. H. C. Newnham, M.A., M.B., M.R.C.S. (Clifton); *W. H. Slimon, M.D., C.M., F.F.P.S. (London); R. T. Smith, M.D., M.R.C.P. (London).

Hon. Treasurer.—W. H. Slimon, M.D., C.M., F.F.P.S.

Council.—S. Jervois Aarons, M.D., M.R.C.P. (London) W. Alexander, M.D., M.Ch., F.R.C.S. (Liverpool); N. T. Brewis, M.B., C.M., F.R.C.P., F.R.C.S.E. (Edinburgh); *E. Stanmore Bishop, F.R.C.S., L.R.C.P. (Manchester); *W. H. Bourke, M.D. (London); *G. Roe Carter, M.R.C.P.I., L.R.C.S.I., (London); A. Donald, M.D., M.R.C.P. (Manchester); *A. E. Giles, M.D., B.Sc., F.R.C.S.E., M.R.C.P. (London); *F. Bowreman Jessett, F.R.C.S. (London); R. J. Kinkead, A.B., M.D. (Galway); J. Macpherson Lawrie, M.D. (Weymouth); *H. M. Macnaughton-Jones, M.B., B.Ch., M.R.C.S. (London); J. A. Mansell-Moullin, M.B., M.R.C.P. (London); F. R. Mutch, M.D., C.M. (Nottingham); J. J. Redfern, M.D., M.Ch. (Croydon); *C. Ryall, F.R.C.S. (London); Mary Anne Dacomb Scharlieb, M.D., M.S. (London); H. J. F. Simson, M.B., C.M., M.R.C.P., F.R.C.S.E. (London); *Heywood Smith, M.D., M.R.C.P. (London); J. H. Swanton, M.D., M.Ch., M.R.C.P. (London); J. W. Taylor, M.Sc., M.D., F.R.C.S. (Birmingham); J. H. Dauber, M.A., M.B., M.R.C.P., E. H. Tweedy, F.R.C.P.I. (Dublin); Hugh Woods, B.A., M.D., B.Ch. (London).

Editor of the Journal.—J. J. Macan, M.A., M.D. (London).

Assistant Editor.—J. H. Swanton, M.D., M.R.C.P. (London).

Hon. Secretaries.—Smallwood Savage, M.A., M.B., B.Ch., F.R.C.S. (Birmingham); H. Beckett-Overy, M.D., F.R.C.S. (London).

Auditors.—C. H. Bennett, M.D. (London); E. F. Travers, M.B.

Trustees of the Property of the Society.—G. Granville Bantock, M.D., F.R.C.S.; R. S. Fancourt Barnes, M.D., F.R.S.E.; Clement Godson, M.D., M.R.C.P.

The asterisk indicates the new names proposed by the Council for the respective offices.

Royal College of Surgeons, England.

THE following Courses of Lectures for 1907 have been arranged to all of which members of the profession are admitted free. The lecture hour is 5 p.m., *Erasmus Wilson Lectures.*—Monday, February 4th, Mr. Wilmott Evans, F.R.C.S., "Leucoderma, and Analogous Pigmentary Changes in the Skin." Wednesday, February 6th, Mr. R. C. Elmslie, F.R.C.S. "Injury and Deformity of the Epiphysis of the Head of the Femur; Coxa Vara." Friday, February 8th, Mr. K. W. Goadby, M.R.C.S., "The Ætiology and Pathology of Pyorrhœa Alveolaris; Rigg's Disease.'

Hunterian Oration.—Thursday, February 14th, Mr. Henry T. Butlin, F.R.C.S., at 4 o'clock, p.m.

Arris and Gale Lectures.—Monday, February 18th, and Wednesday, February 20th, Mr. J. F. Dobson, F.R.C.S., "The Lymphatic System of certain portions of the Alimentary Canal." Friday, February 22nd, Mr. Bertram Abrahams, M.B., "Some Clinical Applications of Physiology."

Hunterian Lectures.—Monday, February 25th and Wedneday, February 27th, Prof. W. Sampson Handley, "The Pathology of Melanotic Growths in relation to their Surgical Treatment." Friday, March 1st and Monday, March 4th, Prof. J. W. Thomson Walker, "The Renal Function in its relation to Surgery." Wednesday, March 6th and Friday, March 8th, Prof. J. Howell Evans, "Cysts and Cystic Conditions of Embryonal Origin." Monday, March 11th, Wednesday, March 13th, and Friday, March 15th, Prof. William Wright, "The Prehistoric and Early Historic Inhabitants of England." Monday, Wednesday, and Friday, March 18th, 20th, and 22nd, Prof. Cecil F. Beadles, (1) "Anatomical Variations in the Larger Arteries of the Brain and their Medical and Surgical Aspects." (2) "Aneurysms of the larger Cerebral Arteries with special reference to their possible Diagnosis and Treatment."

Munificent Gift to Aberdeen University

AT a meeting of Aberdeen University Court, held last week, it was announced that the Hon. A. M'Robert of Cawnpore, India, had founded a fellowship in connection with the University for cancer research. At Mr. M'Robert's death a sum of £10,000 is to be available for the purpose, but that the work may begin at once, he has undertaken to provide £400 a year until such time as the principal sum shall be paid over to the University, either by his executors at his death or earlier. The endowment is to be called the "Georgina M'Robert Fellowship," and it is founded in memory of Mr. M'Robert's wife. In the event of any epoch-making discovery in connection with the subject of cancer research, the Medical Faculty of the University is to have authority to allot all or any portion of the capital as a reward to the discoverer, and also to the investigator or investigators whose work had, in the unanimous opinion of the Medical Faculty, contributed to the discovery. Mr. M'Robert was most heartily thanked for his generous gift. At the same meeting a communication was also read from the trustees of the late Dr. John Wight, Aberdeen, intimating a legacy of £3,000 to found four or more medical bursaries in the University.

Army Medical Service.

IT is officially announced that the Secretary of State for War has approved of the amalgamation of the Army Medical Advisory Board, and the Army Hospital and Sanitary Committee. The reconstituted Army Medical Service Advisory Board is composed of the following members:—The Director-General, Army Medical Service (Surgeon-General Sir A. Keogh, K.C.B., M.D.), (Chairman). The Deputy Director-General, Army Medical Service (Vice-Chairman). Members: Brevet-Colonel D. Bruce, C.B., F.R.S., M.B., R.A.M. Corps (as Expert in Tropical Diseases); Colonel G. K. Scott Moncrieff, C.I.E., R.E., Assistant Director of Fortifications and Works; Lieut.-Colonel C. H. Melville, M.B., R.A.M. Corps (as Expert in Sanitation). Civilian Members: Sir F. Treves, Bart., G.C.V.O., C.B., F.R.C.S., LL.D.; Dr. J. Rose Bradford, F.R.S., F.R.C.P.; Dr. Louis Parkes, Consulting Sanitary Adviser to H.M. Office of Works; Dr. M. S. Pembrey, M.A. (Oxon); Sir Charles A. Cameron, C.B., M.D., F.R.C.S. (for sanitation in Ireland); The secretary will be Lieut.-Colonel C. H. Melville, M.B., R.A.M. Corps, and the India Office will be represented by Surgeon-General A. M. Branfoot, C.I.E., M.B. (retired Indian Medical Service).

Society of Apothecaries of London.

The following candidates passed the primary examination, Part I., January 9th and 10th:—Biology: I. M. Bernard and H. Cox. Chemistry: F. G. Carroll. Materia Medica and Pharmacy: R. C. Carey, E. M. Johnstone, G. F. Malden, and V. P. Norman.

NOTICES TO CORRESPONDENTS, &c.

☞ **Correspondents** requiring a reply in this column are particularly requested to make use of a *Distinctive Signature or Initial*, and to avoid the practice of signing themselves "Reader," "Subscriber," "Old Subscriber," &c. Much confusion will be spared by attention to this rule.

Reprints.—Reprints of articles appearing in this journal can be had at a reduced rate, providing authors give notice to the Publisher or Printer before the type has been distributed. This should be done when returning proofs.

Original Articles or Letters intended for publication should be written on one side of the paper only, and must be authenticated with the name and address of the writer, not necessarily for publication but as evidence of identity.

SUBSCRIPTIONS.

Subscriptions may commence at any date, but the two volumes each year begin on January 1st and July 1st respectively. Terms per annum, 21s.; post free at home or abroad. Foreign subscriptions must be paid in advance. For India Messrs. Thacker, Spink and Co., of Calcutta, are our officially-appointed agents. Indian subscriptions are Rs.15.12.

R. S.—The treatment of uncomfortable cardiac sensations not dependent on organic changes must, to a great extent, be by moral means, but in addition to the drugs you name as having been tried, it might be worth while considering pyrenol. Its action is tonic rather than otherwise, and it has been praised in the condition you describe.

Anthropos.—The Bertillon system (Bertillonage as it is called) does not in itself include finger-prints, but they are used to supplement the ordinary measurements. Bertillon's principal measurements are the length of the head, its breadth, the length of the left middle finger, of the left forearm, and of the left foot. The left side has been found less liable to vary than the right.

Dr. Law.—We hope to have space for your interesting case in our next.

Fatal Anæsthesia.—An original Paper on this subject has been received without the name of the author. We shall be glad if he will kindly communicate with us.

N. T. P.—'Twas ever thus, but we are not discouraged.

W. D. S. is thanked for his kindly note.

FIRE IN EDINBURGH.

A **correspondent** in Edinburgh sends us the following cutting from *The Scotsman* of Saturday last:—"Dr. and Mrs. ——— return most grateful thanks for many kind inquiries and offers of assistance in connection with the alarming and destructive fire at their residence. The present disorder of the house makes it difficult to send individual acknowledgment, and it is hoped that this expression of sincere gratitude will be accepted in lieu of more personal thanks." The correspondent considers this in the nature of an advertisement, and expresses surprise that it should emanate from a Member of Council of the R.C.Phys. of Edinburgh. Under the circumstances referred to in the paragraph we are unable to take the same view.

Connaught.—It is often quite impossible to tell the cause of death with only pathological evidence. Dr. F. J. Smith recently gave some figures from the London Hospital records. These showed that out of 2,123 carefully-performed post-mortems, in 102 cases no naked-eye pathologic appearances were found. The "vomiting and diarrhœa" class furnished the bulk of examples. In 115 cases of this complaint no less than 83 showed nothing abnormal in the organs.

F. H.—Hyoscyamin has been recommended in whooping cough, but we can only say that its administration would have to be carried out with the greatest care.

Meetings of the Societies, Lectures, &c.

Wednesday, January 23rd.

Hunterian Society (London Institution, Finsbury Circus, E.C.).—8.30 p.m.: Hunterian Lecture. Mr. M. Robson: Points in the Diagnosis and Treatment of Duodenal Ulcer.

Medical Graduates' College and Polyclinic (22 Chenies Street, W.C.).—4 p.m.: Mr. A. H. Tubby: Clinique. (Surgical). 5.15 p.m. Lecture:—Dr. A. E. Giles: Developments and Disasters of Extra-Uterine Gestation.

North East London Post-Graduate College (Tottenham Hospital, N.).—2.30 p.m.: Cliniques:—Dermatological (Dr. Meachen), Ophthalmological (Mr. Brooks), Medical Out-patient (Dr. Whipham).

Central London Throat and Ear Hospital (Gray's Inn Road, W.C.).—5 p.m.: Demonstration:—Dr. Abercrombie: Nose and Accessory Sinuses.

Thursday, January 24th.

Medical Graduates' College and Polyclinic (22 Chenies Street, W.C.).—4 p.m.: Mr. Hutchinson: Clinique. (Surgical). 5.15 p.m.: Lecture:—Mr. L. Mummery: The Special Features of Appendicitis in Children.

North-East London Post-Graduate College (Tottenham Hospital, N.).—2.30 p.m.: Cliniques:—Gynæcological Operations (Dr. Giles), Medical (Dr. Whiting), Surgical Out-patient (Mr. Carson). 3 p.m.: Cliniques:—Medical In-patient (Dr. Chappel). 4.30 p.m.: Lecture:—Dr. Meachen: Demonstration of Selected Skin Cases.

St. John's Hospital for Diseases of the Skin (Leicester Square, W.C.).—6 p.m.: Chesterfield Lecture:—Dr. M. Dockrell: Syphilis: Papular (I., Miliary; II., Lenticular; III., Squamous; IV., Moist, Pustular and Tuberculous).

Friday, January 25th.

Clinical School of London (20 Hanover Square, W.).—8 p.m.: Clinical Evening for the Exhibition of Cases, followed by Discussion. Patients in attendance from 8 to 9 p.m.

Medical Graduates' College and Polyclinic (22 Chenies Street, W.C.).—4 p.m.: Mr. S. Stevenson. Clinique. (Eye).

North-East London Post-Graduate College (Tottenham Hospital, N.).—9.30 a.m.: Clinique. Surgical Out-patient (Mr. H. Evans). 2.30 p.m.: Surgical Operations (Mr. Edmunds). Clinique. Medical Out-patient (Dr. Auld), Ophthalmological (Mr. Brooks) 3 p.m. Clinique. Medical In-patient (Dr. Leslie).

Monday, January 28th.

Odontological Society of Great Britain (20 Hanover Square, W.).—8 p.m.: Dr. W. L. H. Duckworth:—A Note on the Dentition of Some New Guinea Skulls. Mr. H. Bellamy Gardner, L.R.C.P., M.R.C.S.:—Continuous Nasal Administration of Nitrous Oxide with Oxygen. Paper:—Mr. Philip Turner, M.S., B.Sc: Tumours of the Superior Maxilla.

Vacancies.

Carmarthen, Cardigan, and Pembroke Joint Counties Lunatic Asylum, Carmarthen—Junior Assistant Medical Officer. Salary £150 per annum, with furnished rooms, board, washing, and attendance. (no stimulants). Applications to W. Morgan Griffiths, Clerk to the Asylum Visitors, Carmarthen.

Newport Borough Asylum, Caerleon, Mon.—Assistant Medical Officer. Salary £150 per annum, with board, apartments, and attendance. Applications to the Medical Superintendent.

Rochdale Infirmary.—House Surgeon. Salary £100 per annum, with board, residence, and laundry. Applications to Henry Booth, Secretary, Infirmary Offices, 58A, Yorkshire Street, Rochdale.

Cameron Hospital, West Hartlepool.—House Surgeon. Salary £100 per annum, with board, rooms, and washing. Applications to J. G. Taylor, Secretary.

West Riding Asylum, Menston, near Leeds.—Fourth Assistant Medical Officer. Salary £150 per annum, with board and apartments. Applications to the Medical Superintendent.

West Riding Asylum, Menston, near Leeds.—Second Assistant Medical Officer. Salary £200 per annum, with board and apartments. Applications to the Medical Superintendent.

Tunbridge Wells General Hospital.—House Surgeon. Salary £100 per annum, together with board, furnished apartments in the hospital, gas, firing, and attendance. Applications to the Secretary.

East London Hospital for Children and Dispensary for Women, Shadwell, E.—Resident Medical Officer. Salary £100 per annum, with board, residence, and laundry. Applications to W. M. Wilcox, Secretary.

Appointments.

Crossley, Leonard, M.D.Edin., Medical Superintendent of the Sanatorium at the Benenden Branch of the National Association for the Establishment and Maintenance of Sanatoria for Workers suffering from Tuberculosis.

Davis, William Herbert, L.R.C.P.Lond., M.R.C.S., Honorary Assistant Ophthalmic Surgeon to the Royal Albert Hospital, Devonport.

Drapes, Thomas Lambert, M.B., B.C.Cantab., L.R.C.P.Lond., M.R.C.S., District Medical Officer and Workhouse Medical Officer by the Chepstow (Mon.) Board of Guardians.

Fletcher, R. B., M.D., Ch.B.Vict., District Obstetric Officer to the St. Mary's Hospitals, Manchester.

Hay, John, M.D.Vict., M.R.C.P.Lond., Assistant Physician to the Royal Infirmary, Liverpool.

Marwick, R. Elrick, M.B., Ch.B.Edin., Senior House Surgeon to the Dumfries and Galloway Royal Infirmary.

McNaughton, J. G., M.D., M.R.C.P.Edin., Honorary Physician to Ancoats Hospital, Manchester.

Nunneley, F. P., M.B., B.S.Oxon., Certifying Surgeon under the Factory and Workshop Act for the Elstree District of the county of Hertford.

Phillips, Miles H., M.B., B.S.Lond., F.R.C.S.Eng., Honorary Assistant Medical Officer to the Jessop Hospital for Women, Sheffield.

Speirs, Henry, M.B., Ch.B.Edin., House Surgeon at the Chelsea Hospital for Women.

Westerman, Arthur, M.D., Ch.B.Aberd., Clinical Assistant to the Throat and Ear Department at the Brompton Hospital for Diseases of the Chest.

Births.

Edelsten.—On Jan. 15th, at 370 Brixton Road, London, the wife of Ernest A. Edelsten, M.B., M.A., of a son.

Hodgson.—On Jan. 18th, at Leyburn, 6 Mitcham Lane, London, the wife of Charles Hodgson, L.R.C.P.Lond., M.R.C.S.Eng., of a son.

Kempthorne. On Jan. 9th, at Lahore Cantonments, India, the wife of Gerard Ainslie Kempthorne, R.A.M.C., of a daughter.

Marriages.

Bisset—Jackson.—On Jan. 17th, at the East Church, Stirling, Archibald Grainger Bissett, M.B., Ch.B.Glasg., Rothes, Elginshire, to Charlotte Louise, third daughter of the late Surgeon-Lieutenant-Colonel T. W. Jackson, A.M.S.

Grant—Freyer.—On Jan. 19th, at All Saints', Margaret Street, London, Lieut. John Duncan Grant, V.C., 8th Gurkha Rifles, only son of Colonel Suene Grant, R.E., and grandson of the late Colonel J. M. Grant, R.E., to Kathleen, only daughter of Lieutenant-Colonel P. J. Freyer, M.D., late I.M.S., and now of 27 Harley Street, London, W.

Simson—Clarke.—On Jan. 17th, at St. George's, Hanover Square, London, W., Capt. Harold Simson, R.A.M.C., third son of Thomas Simson, of Blackheath, to Kate Litton, eldest daughter of Ernest Clarke, M.D., F.R.C.S., of Chandos Street, Cavendish Square, London.

Deaths.

Begbie.—On Jan. 15th, at Netley Hospital, Major George Edward Begbie, D.S.O., of the 71st Highland Light Infantry, younger son of the late James Warburton Begbie, M.D.Edin., aged 38.

Clinch.—On Jan. 18th, Thomas Aldous Clinch, M.D., D.P.H., elder son of Henry Clinch, of Weeley, Essex, aged 35.

THE MEDICAL PRESS AND CIRCULAR.

"SALUS POPULI SUPREMA LEX."

VOL. CXXXIV. WEDNESDAY, JANUARY 30, 1907. No. 5

NOTES AND COMMENTS.

Secretly or Corruptly.

THE coming into force this year of the Act prohibiting the taking of secret commissions will make very little, if any, difference to medical men. In many commercial circles where grafts, tips, bonuses, and other forms of reward or blackmail are the breath of the nostrils of business, an exceedingly wholesome change of tone may be looked for; indeed, there are few business people, from the fur-coated company-promoter in the City to the aproned domestic at the back-door, who do not give or receive, expect or demand, a share of the "swag" they are instrumental in obtaining for others. Every third scoundrel who appears in the police-court describes himself as an agent, and that blessed term covers a multitude of sins, expressed or implied, in commercial dealings. The world would be little poorer and probably considerably happier if agents disappeared and people transacted business directly with each other. However the millennium is not yet, and it is of the highest importance that every agent should have distinct and recognised limitations. In 1899, when the question of secret commissions was in the air, a gross calumny was perpetrated on the medical profession by a special committee of the London Chamber of Commerce, which was investigating the matter, for they asserted that the system existed of chemists paying medical men commissions on their prescriptions, sometimes to the extent of 25 to 50 per cent. It really is the height of cynical impertinence for a body representing the commercial interests of the City of London, where every kind of commission is given, to make such a reflection on a profession whose hands will compare favourably for cleanness with those of any body of men in the world, and we regret to see the accusation is now being re-made in certain quarters. The taking of commission from hotel-proprietors, chemists, undertakers, *et hoc genus omne*, is disgraceful conduct in the eyes of the profession, and would be treated as such were instances brought to light.

"Nourishment."

DOUBTLESS there are black sheep and spotted ewes in the medical profession, but there is no sort of doubt that professional feeling is totally opposed to those "sharing" practices which are the commonplaces of commercial transactions, and business men know that perfectly well. As to touting for patients, the feeling is equally strong, occasionally almost morbidly so, and when cases of such touting have been proved, the offenders' names have been removed from the *Register*. The bar is the only other profession in which the standard of ethics can compare with that obtaining among doctors, and even the bar is not without its loose fish and undesirables. If we were to believe the statements made by a barrister's clerk in an action brought against his employer last week, the standing of drinks to solicitors by barristers' clerks would appear to be nothing out of the way, and under the happy designation of "nourishment," money is disbursed by barristers for the purpose. In the case under notice, the barrister was prepared to deny the charges, but he was not called upon to do so. Still, the fact remains that even our lethargic General Medical Council could not let such charges against a medical man pass without enquiry. We do not believe that any such underhand dealings either are countenanced by the bar generally, or are carried on on a large scale; but no profession is without its less scrupulous members. The point is that whereas barristers and doctors will not tolerate grafts and commissions, in commerce they are not only tolerated but form part of its ordinary transactions. We trust the word "corruptly" will only allow any escape for those who violate the spirit of the new Act.

Two Persons and One Clerk.

THE facility with which Sir Richard Owen could reconstruct from an odd molar tooth or a long-lost fibula an "animal that was extremely rare," has passed into history. But it seems to be nothing compared to the ease with which a hypnotist can reconstruct the wanderings of a missing clerk. At a dinner of the Lyceum Club last week, a medical man is reported to have told a story in which romance and hypnotism were harmoniously blended. A clerk, so it runs, went out one day to lunch in the City and did not return. Usually in such cases the clerk turns out to have loaded himself with securities and bonds, but this clerk was not of the defaulting order. He took a walk in the park, visited some friends at Clapham Junction, stayed at a hotel there, and then went to Southampton. Four days later he returned home. This tale would not seem to provide very promising "copy" for the enterprising journalist, but it has gone the round of the journals with wonderful celerity. The point of the story is that the clerk was very distrait with his friends at Clapham Junction, and when he got home from Southampton he said he did not know where he had been. The wonders of hypnotism were, however, brought to bear, and in his trance the clerk remembered all that had happened and told it to the operator. The moral of the story is that the clerk was a "dual person," and the Dr. Jekyll part of him did not know when the Mr. Hyde part went to Southampton; moreover, that the two could only be introduced to each other by the hypnotist. The story is considered so wonderful that few have hesitated to believe it.

The Simplest Life.

ONE has heard *ad nauseam* of the simple life, which everybody talks about and nobody practises. Indeed, the simple life seems to resemble the "smart set" in being universally recognised as existing but never tangibly present. It is supposed to be somehow opposed to doctors, and the simple life advocates are the sworn enemies of medicine. Medical men are prepared generally to admit that if their patients all took to the simple life, their bills for attendance would be appreciably smaller, but yet the simple life seems to hang fire. So the British Nature Cure Association has been started, with the object of popularising the movement, and leading to what is called "the simplest life." This is not a reversion to the amœba-stage of existence, but the "practice of the gospel of pure simplicity and a glorious life on less than a shilling a day." Honey and nuts are to be the staple dietary, and cold water inside and out its leading feature, but we are not informed as to clothing to be adopted. Is that to be of the simplest nature, too, we wonder?

No Drugs, No Doctors.

MR. REID, the archbishop of the cult, is delightfully candid about the medical profession. In an interview last week, he informed his interlocutor that "our pet aversions are drugs and doctors. 'No drugs, no doctors!' is our battle-cry. We maintain that doctors are produced by negligence, and kept in being by negligence." It often occurs to us to wonder who are the medical attendants of these silly faddists. And what do they say to them when they are seriously ill? We have it on high authority that the devil when he is ill becomes a model patient, but we cannot help thinking the "no drugs, no doctor" gentlemen must look extremely foolish when they are obliged by stress of ill-health to invoke the aid of a medical man. At the present moment, Mr. Reid is pushing his glorious gospel by means of tracts and missionary nurses in various towns, and admits he is doing very well in the way of subscriptions. By way of showing the profession how tuberculosis should be treated his association have conceived the original idea that an open-air sanatorium would be a good thing, and they have collected £9,000 towards the £25,000 required for that object. This treatment is to be called "Natureopathy," and no doubt medical men will consider the propriety of following Mr. Reid's lead, and building a sanatorium or two also, as the plan is so striking a novelty.

LEADING ARTICLES.

CHANGES IN DUBLIN UNIVERSITY.

EVENTS have moved fast during the past few days with regard to university matters in Ireland. First came the Report of the Commission appointed by his Majesty last June to inquire into the affairs of Trinity College, Dublin, and the University of Dublin, and their relations to education in Ireland, and hard on its heels was the declaration of the policy of the Government made by Mr. Bryce. The Commission has certainly not been dilatory in presenting its Report, and no one who reads it can deny that the members have fulfilled their duty thoroughly and conscientiously. The task before them divided itself naturally into two parts—one dealing with what is known as "the Irish University question," the other with the internal affairs of Trinity College. With regard to the first question, the Commission has not been able to arrive at a unanimous conclusion further than that they "cannot hope to render the College [*i.e.*, Trinity College] acceptable to the Roman Catholic Episcopate by reasonable changes in its constitution." With regard to the alternative suggestions, four of the nine Commissioners are in favour of the re-constitution of Dublin University so as to include along with Trinity College a new college acceptable to Roman Catholics and to the three existing Queen's Colleges; three are in favour of the establishment of a college acceptable to Roman Catholics in the Royal University; and one thinks the demand for such a college is unreasonable. The remaining Commissioner thinks the re-constitution of Dublin University the ideal scheme, but in view of the avowed hostility to it of the staffs of all the existing colleges, he thinks it impracticable at present. With regard to questions of internal reform, which, however, sink now almost into insignificance, it is satisfactory that the Commissioners sign a unanimous Report. The recommendations made show a deep insight into the present cumbrous constitution of the College, and will undoubtedly, if carried out, make for efficiency in every department of College activity. Abolition of the Board, with the substitution of an elective body representative of both Fellows and Professors, and radical reform in the system of electing to Fellowships, are the main features. The need for further provision for scientific research is rightly emphasised. It is recommended that, as already agreed upon by the College, the College of Physicians, and Sir Patrick Dun's Hospital, the connection between these bodies shall cease. The King's Professors are to be appointed by Trinity College, instead of by the College of Physicians, and a fair division of the funds hitherto applied to their salaries is to be made. Sir Patrick Dun's Hospital is to be freed from the control of both colleges, and its Governors are to be its sole authority. We congratulate Trinity College on the splendid verdict pronounced that "as it stands to-day it is a noble institution for the maintenance of sound learning not unworthy of its great traditions and of the affection and veneration with which it is regarded by its children," and we hope with the Commissioners that "it will in the future increase in strength and usefulness." In the difficult days which await it in the immediate future, this statement from a Commission not altogether friendly must not be forgotten.

The most important point for Irishmen, however, is which of the alternative policies with regard to the University as a whole the Government intend to adopt, and if we are to accept the statement just issued by Mr. Bryce, the retiring Chief Secretary, they intend to unite four colleges in the University of Dublin, viz., Trinity College, a new college in Dublin for Roman Catholics, Queen's College, Belfast, and Queen's College, Cork. This scheme was condemned by four out of the nine Commissioners; it was recommended by four, and the ninth Commissioner, though in favour of it, said the time was not ripe for it. In the words of Sir Edward Fry, the Chairman of the Commission: "Trinity College rejects it. Lord Justice FitzGibbon, in refusing to accept it, speaks probably the general voice of his Protestant brethren. Mr. O'Reilly, expressing, as he believes, the opinion of the great mass of the Roman Catholic laymen of Ireland, considers it the worst of all proposals and intrinsically impracticable. The Rev. Dr. Delany, who may be taken to represent the higher Roman Catholic teachers in Dublin, reprobates it. The Rev. Dr. Hamilton, speaking for Belfast, Dr. Windle for Cork, and Dr. Anderson for Galway, are unanimous in their disapproval; and if possible still more important is the condemnation unanimously passed upon the scheme by the Senate of the Royal University at a large meeting of that body, which probably more thoroughly represents the higher education in Ireland outside Trinity College than any other body in Ireland."

SCHOOL BOARDS AND MEDICAL CERTIFICATES.

DURING the past few years the public has become familiarised with the complaints of Education Boards in various parts of the Kingdom as to the worthlessness of medical certificates. A typical instance may be offered in a reference from the Aberystwyth Committee approved by the Cardiganshire Education Committee, deprecating "the wholesale manner in which medical certificates were granted in trivial instances, as having a tendency to defeat the administration of the Education Act." In the accompanying discussion some hard things were said about the medical profession. The Rev. Daniel Evans observed, for example, that in the Llandyssul district "there were several children he knew of who went out to service, but who were certified by the medical officer as unfit to attend school." These words are taken from the *South Wales Daily News* of January 18th last, and constitute a grave charge either against the parents or against the competency or the good faith of a medical officer about whose identity there can, presumably, be no possible doubt. In either case the Rev. Daniel Evans should be called upon to justify or to withdraw a charge made in a public official capacity. If the officer concerned be a member of one of the medical defence unions, we should advise him to apply for counsel in the matter. Principal Bebb declared that "the wholesale manner in which medical certificates were granted in the county at present reduced the matter of education to an absolute farce, and it was time it was put a stop to." This general assertion, of course, stands upon a different footing from the direct charge of the Rev. Daniel Evans. It may be asked of the irate gentlemen who make these complaints have duly considered the question of school certificates. These documents are signed by members of a learned profession, and are absolutely necessary for the administration of any scheme of national education, inasmuch as no compulsory system could exist for a day unless exemption from attendance were made in the case of sick and ailing children. Yet these certificates are obtained from the medical profession without payment of any fee by the education authorities, or, in the vast majority of instances, by the parents. Why should an important professional service of this kind be exacted from the medical profession? The newspaper report upon which our remarks are founded speaks of certificates from "medical officers," but we presume that the term is applied to medical practitioners. Were they school medical officers, the board would not need to comment adversely upon the conduct of their own officials. We conclude, therefore, that Cardiganshire is simply acting upon the old tradition that local authorities are entitled to free medical certificates. School boards, as well as other public and private bodies and individuals, not to mention patients, are constantly applying to hospital physicians for gratis certificates. We contend that such an application is absolutely unjustifiable and unworthy. The honorary staffs of medical charities give their services to the sick and suffering, and their duty ends at that point. Take one specific instance. Every day in London many non-attendance certificates are granted in the case of children suffering from ringworm, and these are renewed from time to time. Why should the School Board of London, which disburses huge sums annually, be permitted to obtain this important service without adequate payment? A firm, concerted action on the part of hospital boards of the Metropolis could put a stop to the abuse in a week, and in a similar manner the free education certificate could be banished throughout the United Kingdom.

WE understand that the well-known disinfectant "Okol," of the Sanitas Company, is now being put upon the market with a guaranteed germicidal efficiency of 22, as compared with carbolic acid.

CURRENT TOPICS.

The Local Government Board in Action.

The supine attitude of the Local Government Board as a great central authority has often been commented upon in our columns. When some public scandal arises, and not until then, the Board holds an official enquiry and proceeds to act with more or less thoroughness and decision. With the elaborate machinery of inspection at its command, we have often insisted that the L.G.B. officials must have been in possession of the facts of such scandals long before they attained publicity, but had failed to exercise the function of a central controlling body. In this connection it would be interesting to note previous reports upon Prestwich Workhouse, where a grave scandal has recently been disclosed. It appears that on July 21st last a man was removed to the workhouse, and in the following week was transferred to the asylum, where he died the next day. At the instigation of the Lunacy Commissioners, a Local Government Board enquiry was held in October. The report finds grave laxity of administration on the part of the officers responsible for dealing with lunatics at the workhouse. They find that the allegation that the death of deceased was accelerated by injuries received prior to his removal from Prestwich Workhouse was borne out by the evidence, and that the injuries were due to direct violence. The Board could not avoid the conclusion that they were inflicted by Attendant W. F. Watts, and that the Head Attendant, T. Snape, and J. Haslam have been shown unfit to hold office. The medical officer is seriously censured. He is found to have delegated too much of his power to the head attendant, and in this particular instance not to have visited the deceased until he had been 54 hours in the workhouse, most of the time in the padded room. Later, neither he nor the master appear to the Board to have been informed that the patient had to be forcibly fed. Further, they find the medical officer added to deceased's examination on discharge, "Fracture of ribs (doubtful)," but admitted the words were appended the day following discharge, when the asylum report of fracture was received. It is satisfactory to know that the L.G.B. is not afraid of acting on an enquiry report. It would be still more encouraging were such irregularities to be checked before the occurrence of scandals. What reports and recommendations have been furnished by L.G.B. inspectors of Prestwich Workhouse during, say, the past ten years ?

Insurance Companies and the Hospitals.

The Workmen's Compensation Act, which comes into operation in July next, will, it is calculated, extend the benefits of accident insurance to 6,000,000 people who have not enjoyed that advantage previously, and all employers who are wise will rush to insure their risk under the Act with some sound company. These companies' business will be proportionately extended, and as all those doing accident work are proprietary and not mutual societies, the profits of the holders of insurance shares will rise proportionately. Without wishing in any way to decry this beneficent form of commerce, it is nevertheless pertinent to point out that accident companies benefit very largely from the work of the hospitals, and though we believe some of them subscribe to hospital funds, it is a question whether their obligations to hospitals should not be more generally and substantially recognised. It is a great and patent advantage to a company which has to pay a workman's sickness allowance while he is ill that such workman should have the best and most skilful treatment, and such can undoubtedly be obtained, gratis, at a hospital. As a rule—there are some exceptions, of course—the workman, the employer, and the insurance company give nothing to the hospital, though they all benefit directly or indirectly from hospital work. Moreover, the insurance companies avail themselves without stint of the opinion of hospital medical officers as to workmen's condition, progress, and fitness for work, and for these services they pay nothing. Now, it would seem that when hospitals are one and all suffering from lack of funds, it is not fair or just that proprietary companies trading for profit, and paying handsome dividends to their shareholders, should obtain charitable advice and treatment for nothing for those on their books. How far the articles of association of the companies allow them to contribute to hospitals is probably a difficult question, as is also the apportionment of the amount that should be contributed by each company to each hospital. But that something should be done is obvious, and the matter should be gravely considered by hospital boards and the companies themselves.

Gambling and Climate.

The bitter cry of the British spa may assume a less plaintive note in the future if the present French Government adhere to their intention firmly to enforce their new anti-gambling law. It has always been easily explicable on rational grounds why English people should prefer the Riviera and Algiers to their native watering-places in the winter, but it has been somewhat less obvious why they should spend their summer and autumn at many inconvenient, over-crowded, and not particularly salutary spas. The waters have been the ostensible excuse, but even the most scientific analyses have frequently failed to demonstrate that there is any overwhelming virtue in some of the springs that have contained calcium chloride or sodium sulphate in the similar proportions to those that bubble out of the bowels of our own territory. The explanation in many cases, of course, is that roulette, baccarat, or petits chevaux have been allowed as pastimes, and even the most gouty and hypochondriacal dyspeptic realises the difference in the degree of mental exhilaration derivable from those amusements and that drawn from the drawing-room "music" or the wheezy orchestra of the British hydro. On moral grounds we must commend the latter, but on medical ones it is not a little questionable whether some patients might not be drawn out of themselves more by a course of *rouge-et-noir* and *pair* and *impair*. However, the first attempts to suppress gambling in the pleasure resorts in France have been partly repulsed, and it may be the Government's courage will ooze out if its finger-tips when it comes to a fight. If, however, gambling is finally suppressed, hydro shares may rise.

Disease and the Churches.

LAST week's issue of the *Church of Ireland Gazette* contained a letter signed "Æsculapius," in which, under the heading of "Cleanliness and Godliness," the writer draws attention to the neglect of the clergy to wipe with a napkin the cup used in administering the Sacrament. He goes on to call attention to the fact that, while successful efforts were being made to banish the kissing of the Testament in law courts, nothing has been done by the clergy to remove what is undoubtedly a most dangerous source of infection in churches. He then continues: "On Christmas Day some 150 to 200 communicants attended the 8 a.m. service in the church to which I belong. Immediately preceding me was a poor woman whose mouth I could not possibly help observing was in a neglected condition; and her state was nothing in comparison to that of patients of my own who attend Communion during (and I hope afterwards) their physical illness." We desire to associate ourselves with the observations of "Æsculapius." It is little short of appalling to contemplate what might any day be the result of the present manner of administering the cup during the Sacrament. Any medical man, or any clergyman, can, without difficulty or exaggeration, summon up in his mind a picture of the terrible results that might happen in a family because the mother with chapped lips received the Sacrament after a person with a syphilitic ulcer of the tongue or lips. The churches we are glad to say, are in many ways taking a very active course in the spread of the knowledge of hygiene, and some of the simpler forms of preventive medicine, but what is the use of this if, in their own practice, they do not conform to the most elementary principles?

Nitrogen from Air.

To obtain nitrogen from the atmosphere as nitric acid has long been a dream of the scientific chemist. From a recent announcement made exclusively by the *Daily Chronicle* we learn that a method has at length been perfected by Sir William Crookes. If so, his discovery may possibly be one of the greatest economic value ever yet placed by science in the hands of mankind. It will mean that the great envelope of air around the globe will be made henceforth to contribute largely to the production of food. It is hardly necessary to recall the fact that the remunerative raising of successive crops from any given area of cultivation is possible only by the systematic supply of nitrogenous manures, of which the most valuable is afforded by the nitrate beds of South America. The demand upon the latter, however, has been so great that before many years these deposits must be exhausted. Should it be possible to obtain unlimited quantities of nitric acid at a sufficiently cheap rate, an alternative supply of nitrates would be available for agricultural purposes. So long ago as 1892 Sir William Crookes proved that nitric acid could be obtained from air, and he has been superintending a series of investigations for the last six years at Freibourg. The confirmation of this discovery would place his name upon one of the highest pinnacles of fame as a scientific benefactor of mankind, especially if nitrogen were given freely to the world at large.

Centralisation of Liverpool Hospitals.

The Liverpool hospital world has been thrown into a state of unusual stir and activity. Last week a dinner was held to celebrate the establishment of a United Clinical School in connection with the local University. The advantages of such a scheme are obvious, especially when we learn that in so large a centre of population about 40 per cent. receive gratuitous medical relief. On the day of the dinner the City Council reduced the estimates for the Corporation (infectious) hospitals by £10,000. The chief public interest, however, has been centred upon Professor Paterson's suggestions that all the voluntary medical charities should join their forces under one central control. He claims that increased efficiency as well as economy would be secured thereby, but he proposes to include in the cooperation scheme the poor law infirmaries. At present they are excluded from such association by the law, but the amount of clinical material obtainable from their field of work may be estimated from the fact that the poor law institutions have 3,000 beds and treat annually more than 10,000 patients. The opening up of the whole question of hospital administration in Liverpool is a sign of the times, and it seems not unlikely that the citizens of that great city will be the first to test some well-considered scheme of local hospital centralisation. The subsequent course of events with regard to its administration, its social and its educational aspects, deserves the close attention of medical men generally, inasmuch as their interests are vitally concerned in the question of hospital reform.

MR. PIETRO MICHELLI, C.M.G., Secretary to the Seamen's Hospital, is to be entertained at dinner at the Trocadero Restaurant on February 15th, in celebration of the honour recently conferred upon him.

DR. BAYLISS, F.R.S., will deliver a course of lectures to medical men on Certain Fundamental Problems in Physiology Common to Animals and Plants. The lectures will take place on Wednesdays at 5 p.m., at the London University.

DR. JAMES J. FITZGERALD, has been appointed Medical Superintendent of the Cork District Asylum, although a previous election had been disallowed by the Lord Lieutenant of Ireland.

PROFESSOR MCKENDRICK is to receive a testimonial from Glasgow University in recognition of his long and distinguished career. It is not yet decided what form the memorial shall take.

A CLINICAL LECTURE

ON

CHRONIC NON-SUPPURATIVE DISEASES OF THE MIDDLE EAR. (*a*)

By MACLEOD YEARSLEY, F.R.C.S.Eng.,

Senior Surgeon to the Royal Ear Hospital.

The subject upon which I have to speak this afternoon is one of very great interest and considerable difficulty, not only on account of the various forms under which chronic non-suppurative disease of the middle ear makes its appearance, but also from the confusion which the various writers upon the subject have brought into its classification. Indeed, the student who has read all that the different text-books have to say upon the matter finds that his ideas as to these conditions have only been rendered more hazy and that he knows, possibly, less than before as to the true classification of the forms of non-suppurative disease which give rise to chronic deafness.

At the same time, it is undoubtedly a fact that, during the last ten or fifteen years, considerable progress has been made in the elucidation of this problem of otology, and this progress has been most striking in two ways—the recognition of the causes which lead to chronic non-suppurative middle-ear disease and the work which has been done in the segregation of its forms.

One of the greatest difficulties in the way of investigation is the lack of pathological material wherewith to differentiate the various conditions, especially in their early stages. Persons suffering with chronic deafness due to non-suppurative middle-ear changes do not die from their disease, whilst, should they succumb to other causes during the early stages of the ear malady, it is extremely unlikely that it has been diagnosed, at any rate the chance of a competent pathologist and otologist obtaining their temporal bones is extremely small. This is especially the case with that insidious malady termed "otosclerosis," or rarefying labyrinthitis. Although we know considerably more than we did ten years ago, we still are greatly in the dark as to the true etiology and pathology of this bugbear of otology.

There is great diversity in the classification of these forms of deafness in the text-books, and in systematic teaching it is a matter of some difficulty to put a good arrangement, clear and understandable, before the student. The one I have decided to adopt commends itself for simplicity and comprehension. This classification recognises two main forms of chronic non-suppurative middle-ear disease as follows :—

1. Hypertrophic catarrhal deafness.
2. Otosclerosis (rarefying labyrinthitis).

Of these the first—hypertrophic catarrhal deafness—is the most common. It is inflammatory in nature and its pathology is better understood than is that of the last form—otosclerosis—which is probably more of the nature of a trophoneurosis. Some confusion has arisen between these two forms because, in the first place, there is a good deal of similarity as regards symptoms between the later stages of the two diseases, and in the second place, they may both be co-existent in the same patient.

The secret of the successful treatment of hypertrophic catarrhal deafness lies in the treatment of abnormal conditions of the nose and throat and in catching the condition early. Unfortunately, persons suffering from gradually increasing deafness do not seek skilled help early enough in the majority of cases, generally because they hope to get well by themselves, often because it is only by the second ear becoming attacked that they realise that the other has become seriously involved.

Let us this afternoon consider in detail the first of the two conditions I have enumerated, viz. :—

HYPERTROPHIC CATARRH.

The majority of these cases begin in early life, the reason being that adenoids, which is essentially a disease of that period of our existence, is one of the most fruitful causes of the condition.

Etiology.—The primary cause is catarrh of the upper air passages ; therefore anything which promotes this condition will act as a subsidiary cause. Some people like to have arranged for them a long list of causes, divided into local and general. In the case of hypertrophic catarrh such a list can be easily made up as follows :—*General* : 1. Exposure to wet and cold ; (2) anæmia and plethora ; (3) diathesis (gout, rheumatism, syphilis, &c.) ; (4) exanthemata ; *Local* ; (1) Hypertrophy of the lymphoid ring of Waldeyer (adenoids, enlarged tonsils) ; (2) secondary syphilis ; (3) œdema and hypertrophy of the turbinal bodies ; (4) atrophic rhinitis ; (5) nasal polypi, &c., (6) suppuration in accessory nasal cavaties ; (7) irritation of nasal mucosa by smoke, dust, &c.

The most important of the foregoing causes are adenoids, enlarged tonsils, and other forms of nasal obstruction. These conditions act by keeping up the catarrhal state rather than mechanically, although they also act in the latter manner sometimes, chiefly by interfering with the proper working of the palatal and tubal muscles. One of the best proofs of the way in which nasal obstruction acts in keeping up the catarrhal condition is to be found in the persistence of adenoids in the adult. The rapid enlargement of the nasopharynx at the onset of puberty generally leaves the pad of adenoids which formerly filled the cavity much smaller, although the difference is really more apparent than real. Hence the symptoms of obstruction (assuming that there is no concomitant nasal hypertrophy) become ameliorated, whilst the ear condition progresses on account of the frequent attacks of nasal catarrh induced by the presence of the adenoids.

Pathology.—The pathological changes in hypertrophic catarrh may be divided into four stages : (1) chronic congestion and exudation ; (2) pro-

---

(*a*) Being the first of two Post-Graduate Lectures delivered at the Royal Ear Hospital on December 13th, 1906, and January 3rd, 1907.

liferation; (3) fibrous contraction; (4) cicatrisation ("post-catarrhal").

We have only to consider for one moment the peculiar anatomy of the tympanic cavity to realise the effects of catarrhal inflammation upon it and upon the proper working of the various ossicles and muscles contained therein. In the attic, surrounding the articulation of the ossicles and intervening between their ligamentous attachments, are tiny pouches of mucous membrane, in which even a small amount of swelling is a serious matter for the efficient working of the auditory mechanism.

Let us take these four stages in more detail, although the time limit prevents our entering deeply into them.

In the *Stage of Congestion* there is engorgement of the vessels, with exudation into the subepithelial layer. Occasionally this exudation is sufficient to pass into the tympanic cavity, forming a serous, mucous, or sero-mucoid accumulation. Such a condition is uncommon in this country, although it is very common in America. If resolution occurs, the vessels are relieved and the exudation is carried off by the lymphatics; if there is no such happy ending, engorgement and exudate remain, and the condition passes into the *Stage of Proliferation* of cell elements, in which new fibrous tissue is formed in the subepithelial layer as a result of the chronic inflammation. As this developes, the new tissue commences to contract and the *Stage of Contraction* is reached, resulting in the binding down of ossicles and muscles by bands of adhesion, the reduction of the lining membrane to a mass of contracted fibrous tissue, and the narrowing of the Eustachian tube. Finally this third stage passes insensibly into the *Stage of Cicatrisation*, or post-catarrhal condition.

(The lecturer then went on to detail the effects of these changes upon the membrana tympani, and described the appearances of the thickened and indrawn membrane).

We must now pass on to *Symptoms*. These may best be discussed according as the disease affects the Eustachian tube most or as it affects the whole tympanic tract. Let us take the former first.

(*a*) CHRONIC CATARRH OF THE EUSTACHIAN TUBE.

When the condition chiefly affects the Eustachian tubes the symptoms are almost wholly referable to the obstruction thus caused. The tube may be affected at its pharyngeal opening only, or in its whole length, and a tube affected in the first manner may later be involved throughout its length by the spread of the catarrh. There is marked deafness on one or both sides, with generally irritation in the tubal region. On swallowing or blowing the nose there may be an amelioration for a few moments, heralded by a crack in the ears. With the deafness is more or less tinnitus, usually of a dull, rushing character, with a full, oppressed feeling in the head, and autophony, or the hearing of one's own voice in the ears, as if the head were shut up in a box. As the causative cold becomes less the hearing may be restored with a sudden crack, due to the parting of the opposed surfaces of the tubal mucous membrane. In first attacks this restoration, or the effect of inflation, is immediate and permanent, but in later attacks it becomes less and less, until the patient reaches a stage when the deafness is more or less always with him. The *diagnosis* and *prognosis* of tubal obstruction depend mainly upon the result of inflation and the appearances of the membrane, which is indrawn and, when the catarrh affects only the tube, normal in texture and lustre.

The *treatment* of Eustachian catarrh resolves itself into that of the *cause* (removal of the conditions leading to catarrh of the upper air passages and general constitutional measures) and that of the *effect*. This resolves itself into inflation, the use of the Eustachian bougie, and intra-tubal injections As regards inflation, let me say one word. I have personally long given up the use of the Politzer bag, save in a few isolated cases. It is a dirty method. One never knows—even if the nasal passages be first carefully cleansed—what one may blow into the ears, nor the exact force one may be using. I have seen a house surgeon rupture an atrophic membrane by too forcible Politzerisation, and I feel sure that the superfluous force which the Politzer bag requires is spent in overstretching the drum-head. I habitually use the Eustachian catheter for all inflations. It is clean, one can regulate the force of inflation to a nicety, and one can, further, pass through it a bougie, or make by its means an intra-tympanic injection.

Eustachian bougies are made of celluloid, and, after dipping in parolein or similar oily fluid, are passed along the catheter into the Eustachian tube. When in position they should be allowed to remain for a couple of minutes. They are then withdrawn and inflation performed. Whether the bougie be used or not, it is well to inject through the catheter a few drops of parolein, preferably containing 5 per cent. of menthol. Two or three drops should be introduced into the wide end of the catheter, and inflation performed. By this means the fluid is sprayed into the Eustachian tube and, by its oily nature, prevents the opposed mucous surfaces becoming again adherent.

(*b*) CHRONIC CATARRH OF THE WHOLE TYMPANIC TRACT.

The signs and symptoms of this condition depend upon the stage at which the malady has arrived. In the *Congestive Stage* the severity of the symptoms is dependent upon the amount of exudation. As I pointed out above, cases which exudate in the tympanic cavity are decidedly uncommon in this country; indeed, during an experience of over fifteen years, I have not seen enough cases to count on my ten fingers. When, however, exudation is marked, there is a feeling of fulness, marked deafness, with bubbling, tinnitus, autophony, and general vertigo. In the absence of fluid exudation in the tympanum, the symptoms are less severe, there is deafness and tinnitus, with crackling, and the improvement upon inflation is more marked than in the former type of case. Upon examination, in cases of exudation, the membrane of Shrapnell and the manubrial plexus are injected, and the exudation shows itself as a dark line running across the membrane in a slight curve with the concavity upwards. When this exudate is very fluid, the line may vary with the position of the patient's head. It may contain bubbles of air which can be seen through the semi-transparent membrane, sometimes giving it almost the appearance of Gruyère cheese. When there is no exudation, the membrane appears slightly injected along the handle of the malleus, and may be also slightly indrawn.

The treatment of the congestive stage of chronic catarrh affecting the whole tympanic tract is both causative and local. Any condition in the nose or naso-pharynx which is likely to bring about a continuance or a fresh attack of the trouble should be sought, and the patient made to fully understand the necessity for removing it. If operation is undertaken, it should be postponed until the aural condition has been ameliorated somewhat, especially in cases with marked exudation. During this time a nasal alkaline douche should be used daily. In both varieties of case inflation should be practised. When there is exudation of a very fluid character, it may be evacuated by inflation with the patient's head inclined to the opposite side, but when it is mucoid and tenacious it is not so easy to remove. This may sometimes be accomplished by means of an intra-tympanic injection of a warm, mild, alkaline solution, but it is occasionally necessary to incise the drum and remove the exudate by mopping with a wool-armed probe. The question of incising and then blowing out the exudate by inflation is a debated one. Personally, if there is any difficulty, I do not see that there is any risk, provided the inflation is done through a clean catheter through a previously carefully cleansed nose. It may be sometimes sucked out by means of a Siegle pneumatic speculum. After the removal of the exudate, counter-irritation behind the ear is of advantage.

In the *Stages of Proliferation and Contraction*, the symptoms of which may best be taken together, the history is usually one of repeated attacks of deafness, generally due to colds, the first attacks interrupted by periods of good hearing, but each succeeding attack being longer in duration, and less perfectly recovered from. A stage is reached when the deafness becomes permanent and is worse after each fresh cold. The deafness is accompanied with varying tinnitus, and there are in these late stages certain added symptoms. Chief among these is *Paracusis Willisii*, or hearing better in a noise. There are several theories as to the exact meaning of this symptom, the older one is that it is due to torpor of the auditory nerve from disuse, a louder noise waking it up, so to speak, and enabling it to distinguish lesser sounds. Another theory makes it due to anchylosis of the ossicles, the loud noise shaking them free enough to respond to other sounds. Personally, I am inclined to think that the real cause may be ultimately found to lie in changes in the intra-labyrinthine fluids, about which we know very little indeed at present. Most otologists look upon Paracusis Willisii as a very bad symptom from the point of view of prognosis, but the more advanced among us are beginning to consider it as rather an indication for treatment. *Otomyasthenia* is another symptom of the later stages. It is due to implication of the intra-tympanic muscles, according to Rumbold, who looks upon these structures as accommodating the ear to different sounds. Otomyasthenia means practically the loss of the ability to distinguish one sound among many others; thus, when carrying on an individual conversation in a room where a number of other persons are talking, the patient suffering with otomyasthenia will be unable to pick out his companions' words from the buzz that is going on round them.

Diplacusis, usually disharmonic, is a third symptom. *Tinnitus* varies; it may be incessant, marked, or slight, and is usually of a rushing, roaring, or machinery-like character.

On examination the membrane may be found to be markedly indrawn, or but slightly so. As a rule it is dull, whitish, and thickened. It may contain calcareous deposits, and present local atrophies. It is most important to further examine it with the Siegle pneumatic speculum, in order to obtain information as to its mobility, and that of the ossicles. It may be found that the handle of the malleus does not move at all.

Tuning fork tests (already described to you in an earlier lecture by Mr. Lake) give the reactions common to disease of the sound-conducting portion of the ear. Gelle's test will give information as to the fixation or not of the stapes.

(*To be continued*).

Note.—*A Clinical Lecture by a well-known teacher appears in each number of this journal. The lecture for next week's issue will be by Macleod Yearsley, F.R.C.S.Eng., Senior Surgeon to the Royal Ear Hospital, London, the subject being "Chronic Non-Suppurative Diseases of the Middle Ear." Part II. A post graduate lecture.*

ORIGINAL PAPERS.

VENTRO-FIXATION OF THE UTERUS IN THE TREATMENT OF ITS BACKWARD DISPLACEMENTS. (a)

By HENRY BRIGGS, M.B.Edin., F.R.C.S.Eng.,
Surgeon to the Liverpool Hospital for Women, &c., &c.

The exemption of the "blooming, happy, and fertile" woman from any treatment whatever was claimed.

During the child-bearing period of life he advocated the limitation of pessary treatment to recent cases of retroversion or retroflexion, after manual reduction of the displacement, and for chronic backward displacement of the uterus with complications he urged the superior position of ventro-fixation, and founded his opinion upon the clinical records and the after-histories of 203 cases treated by him during the past seven years. In all the 203 cases the patients recovered. The after-histories of all the patients, with the exception of the nine unobtainable and a few too recent to be of value, were added. An analysis of the cases of the five groups A, B, C, D, E, illustrated the extent and character of the complications of backward displacements of the uterus:—

Table A.—98 cases of backward displacement before operation were characterised by—

(*a*) uterine descent in a minor degree in all of them;
(*b*) ovarian prolapse, on one side 13, on both sides 26;
(*c*) inflammatory cystic changes in the ovary, 3;
(*d*) apoplexy and thickened capsule of ovary, 6;

and were treated by ventro-fixation of the mobile uterus; the relief afforded was complete in 64, partial in 22, and disappointing in 7 patients; one single woman, æt. 23, who had suffered from distressing dysmenorrhœa since puberty, was totally unrelieved by ventro-fixation performed after a previous dilatation and section of the cervix had also failed to relieve her.

Table B.—41 cases, ventro-fixation with perineorrhaphy, colporrhaphy, trachelorrhaphy, dilatation and curettage, *i.e.*, a combination of two or more operations of which one was ventro-fixation showed relief complete in 24, partial in 9, and disappointing in 5 patients.

(a) Abstract of paper read before the Liverpool Medical Society, anuary 17th, 1907.

Table C.—24 cases, ventro-fixation with separation of adhesions and in seven instances salpingostomy (conservative operations); recorded relief complete in 13, partial in 8, and disappointing in 1 patient.

Table D.—31 cases, ventro-fixation with removal of one tube and ovary: relief complete in 20, and partial in 7 patients.

Table E.—9 cases, ventro-fixation with removal of both appendages: relief complete in 7, partial in 1 patient.

Complete relief after ventro-fixation persisted throughout all the groups in almost the same proportion of cases; that is substantial evidence of a pathological element in the aggregate of the backward displacements in Table A. The lowest proportion of complete relief followed the totally conservative treatment of pelvic peritonitis due probably to obscure active or latent germ infection (Table C); in 24 cases pregnancy is unknown after operation, except in one instance.

The author explained his preference for purely parietal peritoneal fixation at the summit of the empty bladder at the lower end of a 2-inch abdominal incision ending one inch above the pubic symphysis. The Trendelenburg position enabled the operator to suture closely this central lowest portion of the parietal peritoneum to the middle two-fourths of the lower half of the anterior surface of the uterine body in which the sutures were planted through muscle one-eighth of an inch deep. No. 2 Chinese silk was used for the fixation; Dr. Briggs said he had discontinued, since 1903, catgut for this purpose only. The abdominal wound was closed in three layers by catgut sutures: the finest catgut always for the skin.

The advantages of peritoneal fixation were the slight uterine mobility it ensured; in the latter advantage Dr. Briggs agreed with Küstner, and the further advantages of less inconvenience to the bladder and the ease and safety of subsequent labour and pregnancy were realised. Dr. Russell Andrews, in his digest in 1905 of all ventro-fixations then published, had found the least interference with labour after peritoneal fixation. Amongst Dr. Briggs' cases in Table A. alone 22 women had borne 32 children; normal labour was the rule, and easy forceps delivery the exception. In one patient who has had five children (twins once) since the operation, uterine inertia during the third stage has been observed, and was not noted before operation by Dr. Masson, of St. Helens.

Dr. Briggs said that cervical and intra-uterine, vaginal and perineal complications were advisedly treated, if necessary, before the abdomen was opened; that abdominal section dealt with the peritonitic bands and their causes; and ventro-fixation completed a safe and satisfactory operation for retroversion or retroflexion during the child-bearing period of life.

AT a London coroner's court last week, a medical witness produced his own copy of the New Testament, upon which he was duly sworn. The incident is not without its suggestive value as to a means of smoothing over a difficulty that is always apt to involve more or less unpleasantness to the objector.

INFECTIVE BRONCHITIS AND ITS RELATION TO CONSUMPTION.

By R. PROSSER WHITE, M.D., M.R.C.S.

Life Vice-President and Hon. Physician to the Royal Albert Edward Infirmary, Wigan, etc.

WITH the essential features and cause of tuberculosis all are familiar, and there is no fact more certain than that the pathological entity we call tuberculosis only exists in the presence of, and is due to the growth and reproduction of the bacillus of tubercle with the resultant biological and chemical changes it produces upon the tissues it invades.

Certain morbid conditions simulating those found in the presence of this organism, but without its actual discovery in the part affected, are termed tuberculides. These are supposed to represent conditions set up by the toxines, or morbid products, generated by this bacillus.

So far the concensus of medical opinion is in agreement, and does not admit of dispute. It is far otherwise when we come to weigh up and estimate the preliminary causes which permit, or encourage, the growth of this organism upon the mucous membrane of the respiratory tract.

The same considerations hold good with bronchitis, which Osler maintains and most of us hold to be in the majority of cases a microbic disorder, although in our present state of knowledge the exciting organisms would appear to be more varied, less specific, and well determined, than those which we know to be responsible for tuberculosis.

My present purpose does not include the consideration of alexines, opsonins, and other anti-bodies, whose *rôle* at the present moment looms so large in the etiology of immunity from disease. I rather desire to draw attention to some more obvious clinical observations, which have reference to the catarrhal or coryzal conditions which so frequently usher in, and are the first incitants of these serious maladies.

It is generally admitted that the only avenues of microbic infection are the skin and the mucous membranes, and if these surfaces are healthy they are impervious to the inroads of infective disease. Pre-existing foci of disease may of course be present in the body, and are liable to be disseminated by the blood or lymph streams. The former leads to a generalised infection, the latter usually producing a slowly progressing and more localised infection. But with this aspect of the subject of infection we are not dealing, excepting that when either of these channels is affected, the progress of a disease becomes more rapid. Even when disseminated by such channels attacking organisms find resistance at every point, and the defensive powers of the body show a distinct tendency to seal up the avenues of approach to prevent further extension.

In discussing the ætiology of bronchitis from an extrinsic point of view only, we must first exclude from our consideration the following intrinsic varieties:

Toxæmic bronchitis, as seen in Bright's disease, gout, and rheumatism.

The syphilitic bronchitis of Graves, Stoke, Munck.

Vasomotor bronchitis, as occurs in asthma.

Bronchitis which arises in the course of typhoid, typhus, malaria, measles (?), scarlet fever (?), and whooping-cough (?).

Also these extraneous varieties:—

Primary mechanical bronchitis caused by traumatism, chemical action, hot steam, air at a low temperature; *e.g.*, such temperatures as are not experienced in ordinary circumstances. The inhalation of mechanical dust, micro-organisms included, but, of course, antecedent to the biological, and chemical changes they produce in the tissues.

With the ætiology, arrangement, and classification of these different forms of bronchitis all will in the main agree. There is, independent and exclusive of these, a bronchitis to my mind the most common, which we may properly and with advantage include under the name of a "direct infective" variety.

Upon this point there will inevitably arise some difference of opinion; in fact, the very existence of an "infective bronchitis" may be denied.

. Among infective causes of bronchitis most medical men include measles and whooping-cough. And secondly, but to a minor degree, that consequent upon true influenza. Of undeniably influenzal bronchitis—that is, where the "Pfeiffer's bacillus" has been found to be the predominating organism in the sputa when examined bacteriologically—my experience has been small, only two cases having come under my personal examination. The first was a subacute case in a middle-aged lady who had never suffered previously from any bronchial affection. The second occurred in a man, a chronic bronchitic subject, troubled also with bronchiectasis and emphysema of many years' standing. In both these cases the sputum was found swarming with Pfeiffer's organisms. In both cases the course of the illness was unduly protracted, and in the case of the man the symptoms and course were unusually severe. The bacteriological examination in the latter case was confirmed at the public health laboratory at Bournemouth, and in the case of the lady by Dr. Murray, now associated with Dr. Bashford in cancer research. But the existence of a true infective influenzal form of bronchitis, when influenza is epidemic, hardly admits of doubt.

Let us now exclude all these recognised types or forms of bronchitis and ask ourselves what is the origin of the ordinary or usual bronchitis? This question is highly important because in my opinion not one attack in ten seen in daily practice can be referred to any one of the above-mentioned list cf causes. I believe that "the every-day bronchitis," tracheal and bronchial, so-called catarrhal, which affects so many of the population young and old, severely or lightly, will eventually be found directly and solely due to the passage of the same organisms, which are the exciting causes of our "common colds." In my book upon catarrhal fevers I have endeavoured to shew that all true colds are directly infective, are passed on from individual to individual, and this, if not the only method of propagating the disease, is undoubtedly the principal and chief method of its distribution, and that for practical purposes all other so-called and reputed causes may be ignored.

It must at the same time be admitted that out of the large number of organisms found in the secretions of ordinary colds, the actual one responsible has not been definitely proved.

I wish particularly to accentuate this fact, which must have been experienced, but is usually overlooked by medical practitioners, that every ordinary case of bronchitis is preceded by, and can be traced to, an attack of catarrhal fever in the individual. I believe, further, that bronchitis cannot be extended cr augmented without the occurrence of a further attack of catarrhal fever. The proof of my contention bacteriologically is, I know, lacking, but the clinical evidence in its favour is overwhelming. What is most usual is that the fever is epidemic in the family, or in the associates of the person affected, and from one of them he becomes infected. It must always be remembered that the coryzal and nasal symptoms in ordinary colds may have been so slight in a particular individual as to require careful and perhaps expert examination to detect. The close mutual and necessary dependence of bronchitis on ordinary colds is shown in the examination of any large series of cases of common colds. These will invariably be found accompanied with tracheo-bronchitis, more or less severe. In certain favourable subjects, especially children and old people, or persons the subjects of previous attacks, the early catarrhal condition passes sc rapidly along the trachea to the medium, cartilaginous, and terminal bronchioles, setting up so serious an illness as leads us to ignore its possible connection with the organism responsible for a "simple cold."

The action of the organisms associated with simple cold weakens the mucosæ, destroys the ciliated columnar epithelium, and paves the way for secondary micro-organisms, which, finding a suitable medium, develop and multiply, and pass to the lung itself. Shannon, in the "Encyclopædia Medica," says "bronchitis is probably antecedent to broncho-pneumonia, and the bronchiolitis is of a catarrhal nature."

Dr. Ewart remarks in "Allbutt's System of Medicine," "tracheo-bronchitis is essentially a recurrent disease."

Unfortunately, it is indisputable that text-books and authority are as yet against my proposition. For instance, Watson Williams says "bronchitis is generally associated with exposure to cold." When speaking of bronchitis in children he somewhat qualifies this opinion, stating "that it is in the poorly clad, underfed, ill-housed, with dirty and ill-ventilated rooms, that the worse forms are seen. That notwithstanding the researches of bacteriologists, I am convinced that exposure to cold is the immediate cause of bronchitis."

Dr. Ewart, in "Allbutt's System of Medicine," remarks: "The usual proximate cause is a chill; the patient is said to have caught a cold." Later on he appears to find it hard to accept this explanation *in toto*, or to reconcile it with clinical experience, for he further proceeds: "The precise meaning of this phrase is obscure. So long as the adaptive mechanisms are in full efficiency mere extremes of temperature do not constitute a danger to the mucous membranes. Even infants and old people can weather cold air with impunity so long as they are properly clad, and in good health, liability to catching cold is an individual peculiarity." He then continues: "We know very little of the aerial mucous membrane analagous to the heat-regulating mechanism of the skin for temperature." He further quotes Rossbach's experiments which show that the application of cold to the skin is felt in two to three minutes by the reflex contraction of the tracheal vessels, and a little later, by venous congestion and an increased flow of mucus; he concludes thus: "A bronchial catarrh is due to some weakness or fault which leaves the bronchi unprotected against the physical results of exposure to extreme cold." Arguing from this, he accepts the popular idea, and admits that cold draughts, inefficient wraps in night air, wet clothes, and damp feet, are the causes of bronchitis. Personally I have rarely come across attacks of bronchitis without being able to detect infective catarrhal fever previously existing in the same household, and in the same person.

Again, what are the conditions we find conducive to attacks and recurrences of bronchitis? Precisely those which are associated with frequent cold-catching. For instance—

1. Density of population, people who live in towns are more liable than country folks.

2. Sedentary occupations, indoor and crowded rooms and dwellings; people who live out of doors are not affected in the same degree as those who are more intimately associated with their fellows in houses. Ewart says: "Bleakness and exposure to strong winds, especially east and north, are not prone to set up bronchitis; the eastern, northern, and midland counties show more favourably in this respect than the south-western, and those with a higher mean temperature."

It is a recognised fact that neither sailors and passengers at sea, or those who live in the higher Alps, are liable to bronchitis. If the former are affected, it is coincident with the touching at some port, or if the latter from the catching of an "infective cold" by mixing with their friends in the hotels and *pensions*. Osler supports this view, and states: "Indeed, we find it is not those whose daily life constantly exposes them to cold or even rapid changes of temperature, who are most prone to attacks of bronchitis."

There is little, if any, reliable evidence to show that the symptoms of bronchitis are made worse by exposure to cold, though this is both a popular and a professional belief. The only evidence pointing to varying or extremes of temperature in any way contributing to their increasing severity or recrudescence, are the experiments of Rossbach just quoted upon the subject. Whilst, on the other hand, there is the universal testimony and experience of travellers, that in the Arctic regions, in the open-air life at sea, or in any place where the organisms excitive of catarrh are absent, bronchitis cannot occur, and the attacks cease.

I am pleased to find that Sir Lauder Brunton, in the *Lancet* of November 17th, in describing the travels of an infective cold in his own person, supports this view. He says: "The catarrh started in one nostril, then crept round the posterior nares and affected the other nostril, passed on to the trachea, and finally to the bronchi." He also suggests the possibility of those who are in constant attendance upon cases of bronchitis of conveying the germs to others. This suggestion is only partially correct, because in the latter stages of bronchitis the primary infection is swamped and extinguished by the secondary or pyogenic organisms. These latter organisms are themselves virulently infective in suitable circumstances, but require the exciting or symbiotic action of pre-existing organisms to enable them to gain a foothold upon the respiratory mucous membranes. In this sense the latter stages of bronchitis are probably not specifically infective. The distinctly infective stage is the early one where the essentially infective nature of the organisms common to both common colds, and bronchitis is evident and predominant. Referring to this matter, I may mention that I know of a matron who holds advanced views upon this subject. She has charge of aged people in a sanatorium for convalescents. Her practice is, to immediately confine to bed, and to isolate entirely, any of her charges who show the least signs of nasal or bronchial catarrh. The result is that these aged people rarely suffer from bronchitis, or other lung troubles common to those in advancing years. Precautions like these are well worthy of imitation.

Idiopathic bronchitis, acute or chronic, may thus be defined as a disease of the bronchial tubes due to the manifestation of the progressive activity of the catarrhal organisms, to which most of its specific manifestations are directly due. It is chiefly fostered and extended by those circumstances which promote the close and direct association with the agent-carrying individual.

TUBERCULOSIS AND COMMON COLDS.

A serious question for consideration is the following: "Is there any relation, causative, promotive, or repellent, between common colds and tuberculosis?" Both diseases are expressions of microbic infection, and both are fostered by unhygienic conditions such as overcrowding, vitiated atmosphere, lowered vitality. Dr. A. Ransome says "that phthisis occurs least where the population is scantiest." Temperature has no influence upon phthisis, as Dr. Hirsch has proved. I am of opinion that these remarks equally apply to common colds. As in all other zymotic affections, though all persons are probably subject to direct inoculation at one time or another, all do not succumb. There must, therefore, be an individual susceptibility or the reverse. This vulnerability, or immunity in the case of respiratory tuberculosis depends upon the resisting power of the mucous membranes to the invasion of the organism. In the skin a primary lesion of tuberculosis cannot develop without a break in its surface; into this the bacillus can obtain a foothold. This is occasionally seen in the direct inoculation of men by the handling of tuberculous meat, such as butchers. Foci of lupus may also infect through other accidental lacerations of the epidermis, such as the bites of insects. An uninjured mucous surface is likewise probably invulnerable to a casual tubercular infection, just as is the skin. Infection, once through the skin or mucous membrane, passes by the lymphatics and blood vessels to the different parts of the body, and thus the usual manifestations of tuberculosis can be traced. The depredations of the organisms of catarrh affect and restrict their action to the local mucous membrane, and their toxines are confined to and are destroyed in the lymphatic system. We see this in all cases of common colds, as we invariably get a lymphatic extension of a reactive inflammatory nature; but we have little evidence of the further pathological change they bring about in the body. The danger of catarrhal infection appears to lie in its selective affinity for the mucous membrane of the respiratory tract; it finds here its most suitable pabulum upon which to develop. It here produces changes which pave the way for further infections of a more virulent type. Clinical evidence warrants us in believing that the catarrhal state tends to promote, or has a symbiotic action upon the growth of the tubercle bacillus. In a similar manner either of these infections appear to favour the growth of the pyogenic organisms. This is more easily observed in what may be termed primary infection—that is, direct superficial extension or inoculation, as distinguished from secondary—that is, particulate—infection, carried and deposited by the lymphatics or blood stream. These terms, primary and secondary, are, perhaps, somewhat artificial distinctions, but serve a useful classification. It is especially common to find phthisis following upon diseases of the respiratory tract, which exhibit a catarrhal method of extension. Whereas respiratory diseases caused by secondary infections, that is, those carried by the blood current are most rarely followed by phthisis. Kidd says: "It is infinitely rare for phthisis to follow pneumonia, or traumatism of the lungs." Rokitansky makes the same remarks about pleurisy. R. W. Phillips says: "Pleurisy is never the cause though often the sequence of phthisis." "Pneumonia," he remarks, "probably never ends in phthisis, but basal pneumonia is often mistaken for it." Quite different are the results following upon diseases which show a specific primary catarrhal inflammatory action upon the bronchial tubes. Dr. Kidd says: "Pulmonary tuberculosis often appears after measles, influenza, and whooping-cough." And R. W. Phillips admits that the unhealthy catarrhal state of the mucous membrane following upon measles or whooping-cough prepares the way for the tubercle bacillus.

But the majority of cases of apical or catarrhal phthisis have not been the victims of either measles or whooping-cough, and I think most medical men look for and expect to find some predisposing or active inciting cause for the deposition of tubercle in these cases. How then are we to explain their frequent occurrence? My own belief leads me to think that it is due to the great prevalence of catarrhal fever. Catarrh of the bronchi is a very frequent concomitant and forerunner of this form of consumption. That it is constantly aggravating and increasing the condition is surely common experience, both lay and professional. All sufferers volunteer the statement that they have caught fresh colds, and in consequence their cough and general symptoms are worse. Personally I am convinced that the chief beneficial effect of the treatment of consumption in sanatoria is due to the avoidance of catching infective catarrhs. It is a well-accepted fact that in all well-conducted institutions "common colds" are practically unknown. It is quite extraordinary to my mind how writers still misconstrue these facts and their importance; thus Phillips in the "Encyclopædia Medica" says: "It is of the first moment that every individual should understand that consumption is not got by exposure to cold; the bogie of 'catching cold' has done infinite mischief." I believe that the bogie of "catching cold" is very real and a most serious danger. "Infinite harm" is but a mild expression to use when estimating the consequences of "catching cold," that is "infective cold," upon the subjects of either phthisis or bronchitis. At the same time I entirely agree that exposure to cold—that is exposure to changes of temperature, or lowness of temperature—has no connection or causal relation whatever with "catching cold." It is the infective catarrh that we must beware of. At the same time we all of us see so many cases of bronchitis (and bronchitis we believe to be due to the direct passage of catarrhal germs) which pursue the even tenour of their way without ever having grafted upon them tuberculosis, as to cause us to pause over Dr. Phillips's words when he says "great reservation must be adopted before we can accept the dictum of bronchitis as necessarily leading to tuberculosis." Dr. Howship-Dickinson, on the other hand, says, "the vulgar notion of a cold which settles on the lungs and ends in tuberculosis has a profound truth at the bottom of it." Dr. Sims Woodhead declares "a perfectly healthy lung is seldom if ever primarily affected by the tubercle bacillus; the beginning is always a catarrhal affection."

It is well known that the ciliary movements of the epithelium and the vital resistance of the healthy cells of the respiratory tract present a powerful defence against the successful inoculation of bacilli upon its surface.

Chronic or repeated catarrhs, as Hamilton and Socoleff have shown, cause degeneration in these cells, which lessens their activity, and interferes with their power of opposition to foreign inimical agents. It is easy to see how in such cases the tubercular organism can penetrate to the infundibula or the smallest bronchi, where there is no muscular coat to eject, or ciliated epithelium to remove the offending intruder. Dr. Shannon says that "a broncho-pneumonia always precedes the deposit of tuberculosis in the apex of the lungs."

A tuberculosis which enters the lungs by the respiratory tract is well known to be one of the most slowly progressive and chronic forms of tuberculosis, as it is also the most amenable to treatment, because of its catarrhal nature. Apical catarrhal phthisis is recognised by its characteristic slight fever, its crepitations and prolonged expiration. The crepitations are usually said to be due to the forcing apart by the incoming air of the moist cell tissue. A more likely reason to my mind is the passage of air through the moist mucus in the smallest bronchioles and the infundibula. If this latter explanation is correct we may take heart from the observations of Hamilton, who has shown us that the basement membrane in these regions subserves a very important function, inasmuch as it imparts a superficial character to the pathological process, permitting only the passage of fluids through its substance, and allowing no particulate material or organisms into its structure.

The value of this finding lies in its permitting only a local action to the organisms deposited upon its surface, barring their passage to the lymphatics and blood stream, and thus preventing the more rapid modes of dissemination to the surrounding tissues. At the same time it encourages us to believe that the possibilities of prevention and local treatment can be largely extended. The prospect of this disease thus becomes distinctly hopeful, because both prophylaxis and treatment can be made effective.

CLINICAL RECORDS.

A CASE OF SUFFOCATIVE HYDROTHORAX IN WHICH THE PLEURÆ WERE TAPPED SEVERAL HUNDRED TIMES.(a)

Under the care of J. F. O'CARROLL, M.D., M.Ch., F.R.C.P.I.

Physician to the Richmond, Whitworth and Hardwicke Government Hospitals.

The case is that of a man, aged sixty-five, robust, cheery, amiable, and intelligent, who entered hospital in May, 1906, suffering from great distress in breathing and epigastric pain. Considerable swelling and tenderness in the epigastrium led me to think that the patient had some epigastric tumour. The urine, small in quantity and dark in colour, had a fair amount of sugar in it, and it was thought probable that the pancreas was involved. A leisurely examination revealed a systolic apex murmur, faint, and not transmitted very far, together with some dulness in both pleuræ. A month afterwards the right pleural cavity was tapped, and 40 ounces of fluid withdrawn. Two days later the left pleural cavity was tapped, 76 ounces being withdrawn. By way of corroboration of a recantation of the first diagnosis already made, the liver receded up under the lower ribs, and from that time onwards there was no further suspicion of any abdominal mischief, although the epigastric distress recurred whenever the pleuræ became full. The sugar in the urine diminished at every tapping, and frequently disappeared, and seemed to be more or less referable to the amount of dyspnœa and cyanosis present from time to time. Occasionally, as might be suspected, there was a trace of albumen in the urine. A slight purplish tinge was visible through the patient's natural ruddiness, and the veins in his neck were slightly more prominent than they would ordinarily have been. He had also at first some œdema of the legs. Tapping had to be resorted to to such an extent that within the first six months in hospital 60 tappings were actually recorded, and probably some tappings which were not noted. The œdema disappeared, and the abdomen became normal, but subsequently, when the effusions were becoming considerable, the epigastrium swelled out again with the original tenderness. From about the third or fourth month of his residence the conclusion had been arrived at that he had some obstruction of the vena azgyos major, and the diagnosis rested there to the end. It was confidently believed, on purely anatomical grounds, that the mischief must reside there. During the first four or five months the pleuræ were tapped almost alternately. Thereafter the right one was tapped about twice for every time the left was tapped, and this proportion was maintained till March, 1902, when the left pleural cavity ceased to secrete, as the result of an adhesive pleuritis. He had then to be tapped twice as often on the right side, and this went on, practically every second day, to the amount of fifty, and sixty, and seventy ounces till the beginning of May, 1903, almost three years after his admission. Then the right pleura began to show signs of not yielding as much fluid as formerly, and of being annihilated by adhesive pleuritis of rapid course. He died when this was complete, practically as if he had been garotted in such a way as to stop the venous flow into the heart without obstructing the trachea, the process lasting about two days. He had spent three years all but five days in hospital, had hardly lain down in bed for more than two or three hours nightly all that time, but had retained weight, appearance, and good spirits up to the fatal and final closure of the right pleural cavity three days before death.

At the *post-mortem* examination it was difficult at first sight to find any abnormality to account for the clinical history. Oval or roundish plaques of ossifying fibrocartilage were found at the sides of the intervertebral discs in the lower half of the dorsal and in the lumbar region. These may have been attributable to a chronic rheumatoid condition, of which, however, he showed no other sign, or have been caused by his having to sleep in a chair at night during the three years in hospital. On examining the heart and slitting up the vena cava superior, a distinct prominence was noticed, which appeared to bulge forward the posterior wall of the cava and to turn off with an L shape into the posterior wall of the vena azygos. This was an aggregation of tubercular glands of no great bulk, but the real mischief was caused by an actual fusion of the gland mass with the azygos wall exactly at its outfall into the cava. At this very point the azygos was closely adherent to the gland capsule in a crinkled depressed scar, of slate colour, corresponding to that of the gland beneath. The girth of the vein at this point was half that immediately to the right of it. The total amount of fluid withdrawn during the three years was computed to weight about three-quarters of a ton.

OPERATING THEATRES.

ST. THOMAS'S HOSPITAL.

CHOLECYSTOSTOMY FOR OBSTRUCTION OF THE BILIARY PASSAGES CAUSED BY CHRONIC PANCREATITIS.—Mr. BATTLE operated on a woman, æt. 34, who had been admitted for pain in the region of the gall-bladder. Five months before the patient had had attacks of jaundice; she did not lie up for them but got about most of the time at her work. There was no pain at the onset, and after getting better she continued to be more or less jaundiced. Two months ago she was suddenly seized with severe pain in the right hypochondrium, which travelled round to the back. She had several attacks and became very jaundiced. A fortnight ago she had a very severe attack and had been laid up ever since. The urine had a specific gravity of 1012, it was acid and contained no albumen. On admission she was found to be slightly jaundiced; there was marked tenderness over the region of the gall-bladder, where a rounded tumour could be made out; the area of hepatic dulness was increased. Cammidge's test for bile pigments was negative. At the operation Mr. Battle made an incision through the rectus muscle over the gall-bladder, an air bolster having previously been placed under the patient's back. The gall-bladder was readily found, and presented no evidence of previous inflammation. Having packed the surrounding structures away from the gall-bladder by means of strips of sterilised gauze, it was opened at its fundus and its contents evacuated. These consisted of inspissated bile and biliary sand to no great extent; no portion of this sand was sufficiently large to deserve the name of calculus. After thorough cleansing of the gall-bladder, a bullet probe was passed into the cystic duct and from thence to the duodenum without encountering any definite obstruction. The edges of the opening into the gall-bladder were afterwards stitched to the peritoneum, and a small tube left in reaching from the gall-bladder to the surface. The swelling which had been felt before operation in the epigastrium was an enlargement of the head of the pancreas of a somewhat doughy character, and was probably of inflammatory nature. It was evident, Mr. Battle said, that the patient's attack of pain had been due to biliary colic, and the repeated attacks of pain in the same region made it probable that the cause of this pain was the presence of biliary calculi. The nature of the swelling felt in the epigastrium was not very clear before operation, but it was probable, he thought, that the enlargement of the head of the pancreas had caused pressure on the common bile duct and so brought about these intermitting pains, and the jaundice which was still evident at the time of operation. It was quite apparent, he pointed out, from the feel of the pancreatic enlargement, that it was inflammatory and not due to new growth. It was interesting, he remarked, to find such a condition of the pancreas in which Cammidge's test gave a negative result.

Drainage was kept up for some weeks after the operation, during which time the patient improved rapidly, putting on flesh and losing her jaundiced appearance. She left the hospital three weeks after the operation. The last time she was seen the epigastric swelling had very much diminished, and there was neither jaundice nor pain.

TOTTENHAM HOSPITAL

OPERATION FOR REMOVAL OF TUBERCULOUS GLANDS IN THE MESENTERY.—Mr CARSON operated on a girl, æt 10, who had been admitted to hospital with an abdominal tumour and a four months' history of wasting and abdominal pain. The mother stated that the child had been losing flesh rapidly of late, and that the pains in the abdomen, while of short duration, were frequently repeated. There had been no vomiting, but the bowels were rather loose. No blood had been noticed in the stools. On examination the child was thin, but bright and cheerful. The abdomen was retracted, and a hard, irregular tumour could be felt beneath the umbilicus and extending more towards the left than the right. The tumour did not move on respiration, and was not tender. It could be moved within limits from side to side, but not in the long axis of the body. There was no free fluid in the abdomen nor could anything be made out amiss on rectal examination. The lungs were not affected, nor was there any enlargement of the superficial glands (neck, axillæ or groins). The family history was unimportant. A diagnosis of tuberculous mesenteric glands was made, and the abdomen was opened. The tumour consisted of a mass of enlarged and caseating glands in the mesentery, the distance from its edge to the nearest portion of small intestine being 2½ inches. It was about the size of a tangerine orange, and was covered by peritoneum, which was adherent to it, but had not given way at any point. The mass was removed entire, but it was not possible to shell it out from its peritoneal covering on all sides. During removal several vessels, chiefly veins had to be secured, and a fear was expressed that the damage to the blood supply might injure the nutrition of the segment of intestine involved. The abdomen was closed without drainage. Mr. Carson pointed out that the recognition of enlarged glands in the mesentery was not always an easy matter. They were generally secondary to tuberculous ulceration of the intestines, and therefore a history of wasting and diarrhœa with occasional slight hæmorrhage might be obtained. Pain was a common symptom, and this was probably due to the dragging on the intestine causing interference with the free passage of flatus, since tuberculous glands themselves, though perhaps tender, were rarely painful. A diagnosis had to be made between the condition under notice and appendicitis, localised tuberculous peritonitis, fæcal masses and even intussusception. The absence of an acute onset and the chronic nature of the illness would help to exclude the first and last, and a careful examination would readily suffice to distinguish between glands and fæcal masses. The diagnosis from a localised tuberculous peritonitis was more difficult, but the points of most importance were that tuberculous glands formed a hard, definitely localised, fairly movable tumour which presented many points of difference from a typical tuberculous localised peritonitis. Mr. Carson emphasised the value of the treatment by excision, and briefly reviewed the possible terminations in an untreated case, referring particulary to the occurrence of general tuberculous peritonitis and intestinal obstruction due either to kinking of the intestine by the puckering of the mesentery in the process of healing, or to the adhesion of a distant portion of intestine or mesentery to the primary seat.

The patient made an excellent recovery, and is putting on weight steadily.

TRANSACTIONS OF SOCIETIES.

CLINICAL SOCIETY OF LONDON.

MEETING HELD JANUARY 25TH, 1907,

The President, Mr. **Clutton**, in the chair.

Dr. **Seymour Taylor** showed a

CASE OF ACROMEGALY.

The patient, a woman of 32, had suffered from increase in the size of her hands and feet for five years. The case was typical in all respects.

Dr. F. **Parkes Weber** showed a case of

CONGENITAL HEART DISEASE WITH CYANOSIS.

The patient was a girl, æt. 17. When the patient lay on her back a harsh systolic murmur could be heard all over the heart, but when she stood upright the murmur almost completely disappeared or became much fainter and markedly influenced by the respiratory movements, being best heard during inspiration.

Mr. **John R. Lunn** showed a case of

FRACTURE OF TARSUS.

The patient was a man of 22. Some doubtful crepitus could be felt on admission on May 2. He stated that he had jumped a depth of fifteen feet, landing on his left foot. The X-rays revealed a fracture of the astragalus, and a piece of the bone was projecting on the dorsum of the foot. The foot and ankle were put up in a plaster-of-Paris splint, which was removed on June 10th, when there was good movement of the ankle. The patient was discharged on July 15th walking well.

Mr. **John R. Lunn** also showed a case of

ACHONDROPLASIA.

The patient was a male of 53. Intellect good. Height 4ft. 11in. The forehead was prominent, the bridge of the nose rather deficient, the eyes deeply set. The legs are very bowed, there being great curvature of the tibiæ. The feet were short and square, with all the toes nearly the same length. There was very little curvature of the bones of the upper limbs. The fingers are more nearly the same length than normal. The middle and ring fingers diverged at the first interphalangeal joint.

Mr. **Scanes Spicer** spoke of the cases of achrondroplasia that came to the rhinologist with the diagnosis of adenoids on account of the depressed nose and peculiar facial features.

Dr. **Bertram Abrahams** showed an

UNUSUAL CASE OF ENLARGEMENT OF THE HEAD IN A CHILD.

Patient was a male, æt. 3. Nothing wrong was noticed with the head till the age of eight months. It then began to swell, and continued to do so for some four months. Dilatation of the vessels at the root of the nose was first noticed at eighteen months, and has progressed since. *Present condition.*—An intelligent and well-developed child. Head was very large, bulging particularly above and to the back. Greatest circumference 25in. On auscultation a systolic bruit is heard all over the head. The right fronto-parietal fissure is closed, but the left, both coronals, and the frontal portion of the sagittal are patent. The left occipito-parietal region is larger than the right. There is venous dilatation over the glabella, involving the left upper eyelid, and descending to within three quarters of an inch of the tip of the nose. The appearance simulates that of a cirsoid aneurysm. There is no other abnormal physical sign excepting a systolic bruit over the whole præcordia, loudest in the mitral area, and conducted into the axilla.

Dr. **William Ewart** pointed out that the head was not of a hydrocephalic shape, as it retained the normal form.

Mr. **H. L. Barnard** showed a case of

SUCCESSFUL PLASTIC OPERATION FOR A SYPHILITIC PERFORATION OF THE HARD PALATE ON THE LEFT SIDE THE SIZE OF A SIXPENCE.

The patient was a man of 28. The perforation had been present six months. August 16th, 1906.—An L-shaped flap was turned in from the right side of the palate and sutured to the freshened edges of the perforation. The flap was about three times the area of the perforation. Healing occurred well.

Mr. **Barnard** remarked that the experience of modern rhinologists controverted the older views about the tendency of such operation wounds not to heal.

Mr. **W. G. Spencer** thought that the truth lay between the two extremes, and that one could not always expect good results. He described a method that had proved very successful in his experience.

Mr. **Charter Symonds** described a modification of the operation. He was sure the results were much better than was previously considered to be the case. However, some forms gave very bad results; such were those in which the alveolar plate was destroyed, and those in which the perforation was situate in the soft palate.

Mr. **H. L. Barnard** showed a case of

REMOVAL OF A STONE FROM EACH URETER FOR DOUBLE PYONEPHROSIS.

The patient, a woman, æt. 41, had renal colic on both sides, but chiefly on the left, for four years. Attacks of cystitis and pyrexia for three years. Radiographic report: (1) A stone the shape and size of an almond in the right ureter opposite the fourth lumbar vertebra; (2) another, smaller, in the pelvis on the left side, opposite the fourth sacral. October 14th, 1904.—The right ureteric calculus was removed through a loin incision. Wound in ureter closed with catgut, drainage, no leakage of urine. December 5th, 1904.—The left ureteric calculus was removed through an incision in the left fornix of the vagina. Ureter not sutured. Tube in broad ligament for three days. Urinary fistula closed in ten days. *Present condition.*—Well and strong. Weighs 9st. 10½lb. Urine slightly turbid, contains pus, acid, 1016, trace of albumen.

Mr. **W. G. Spencer** discussed the difficulty of closing the ureter through the vagina.

Mr. **Barnard**, in reply, mentioned a case in which Mr. Furnival had pulled down the ureter with a hook into the vagina, and closed the opening in it. It was important in such an event to use catgut, for it had been found that if silk were used another stone often formed at the site of the ligature. Replying to a question of Mr. Fagge's, he said that he had not employed the separator in this case.

Mr. **H. L. Barnard** showed a case illustrating

A METHOD OF DIMINISHING THE RAW SURFACE AFTER REMOVAL OF HALF THE TONGUE.

Patient was a woman, æt. 55. The right half of tongue removed by Whitehead's method. The half of the tongue remaining was doubled back so that the tip was brought in contact with the posterior third. Three catgut sutures were inserted. *Advantages of method.*—(1) Rapid healing and diminished raw surface; (2) smooth and rounded edge to tongue; (3) small scar. *Disadvantages.*—(1) Local recurrence if it occurred would be in the middle of tongue; (2) the sensation of the tip of tongue being down the throat, but it has now moved round to the front.

The **President** said that he had employed this method for twenty-three years, and was satisfied with the results thus obtained. Unfortunately it was rare to get cases early enough for the operation to be suitable for them.

Mr. **C. B. Keetley** remarked that an additional advantage of the operation was the diminished tendency to recurrence. The sooner and better a wound healed the less was the chance of recurrence.

Mr. **Charter Symonds** said that he usually employed the method of stitching the edge of the wound to the mucous membrane on the dorsum of the tongue.

Mr. **H. L. Barnard** showed

A PROSTATIC KNIFE FOR INCISING THE FLOOR OF THE BLADDER IN TOTAL SUPRAPUBIC ENUCLEATION OF THE PROSTATE.

The knife was similar to an adenoid finger curette, but terminated in a blunt, rounded blade. It fitted on the index finger. This was one method of overcoming the difficulty of cutting on the prostate whilst two fingers of one hand were in the rectum.

Mr. C. H. Fagge showed a case of

CARCINOMA OF JEJUNUM; OBSTRUCTION; RESECTION OF PIECE OF JEJUNUM AND ADHERENT TRANSVERSE COLON; DOUBLE LATERAL ANASTOMOSIS WITH MURPHY'S BUTTONS.

The patient, a woman of 33, was now quite well, thirteen months after the operation. The buttons were both passed within six weeks of the operation.

Mr. Fagge, in reply to a question from Mr. Raymond Johnson, said that microscopically the growth proved to be a columnar cell carcinoma, with an unusually great amount of fibrous tissue.

Mr. W. F. Brook showed a case of

MULTIPLE CHONDROMATA OF METATARSAL BONES AND FIRST INTERMETATARSAL SPACE.

Patient was a male, æt. 50. Fifteen years ago right "great toe joint" was crushed. This was followed by occasional painless swelling, which in the course of a few years become permanent. He was first seen in February, 1904, when the condition differed from that now presented in the following respects:—The general swelling was less and not so tense. The calcareous or cartilaginous deposits about the bone were more movable, and the outline of the more superficial ones, which was irregular, was easily recognised. The movements of the joint were scarcely impaired. In the more recent skiagram, as compared with the earlier one, is seen (1) the increasing amount of the calcareous or cartilaginous deposit in the tissues of, and further widening of, the first interspace, and increasing distortion of second metatarsal bone; (2) the slow but progressive destruction of first metatarsal bone; (3) the appearance of chrondromata in the other metatarsals. One of the isolated growths, about ½in. in diameter, was recently removed from the web of the interspace. It was not encapsuled, and upon examination by Mr. Shattock was reported to consist of hyaline cartilage, in which small areas of mucous metaplasia occurred.

Mr. Barnard queried whether the growths might have originated in the tendon sheath.

ROYAL ACADEMY OF MEDICINE IN IRELAND.

Section of Pathology.

President: Joseph O'Carroll, M.D. F.R.C.S.I.
Sectional Secretary: Professor A. H. White, R.C.S.I.

Meeting held Friday, January 4th, 1907.

Dr. J. F. O'Carroll, President of Section, in the Chair.

UNCINARIA DUODENALIS FROM ST. VINCENT (WEST INDIES).

Professor McWeeney, through Dr. Farnan, exhibited specimens of the above sent to him by Dr. Branch, Government Medical Officer at St. Vincent, where the parasite was a regular plague. The exhibit consisted of the washings of the intestine of a child. Two sorts of worms were present—viz., *trichocephalus dispar* in large tufted masses, and *uncinaria* (*ankylostoma*) *duodenalis*. The male and female trichocephalus are very different. The male and female uncinaria are not very unlike each other. The difference was shown by microscopic slides. The male uncinaria was smaller than the female. One measured 7.5 mm. long by 0.47 mm. thick (Manson gave 6 to 11 mm. by .4 to .5). Its remarkable copulatory organ consisted of 2 spicules, beautifully striated under a high power, surrounded by a sort of umbrella-like arrangement supported by 11 ribs. The female was longer and thicker than the male. One measured was 17 mm. long, but was thinner than the male (.37 mm.). However, it may have been a damaged specimen. Manson gives 1 mm. Another measured .469 in width, so that the females did not seem to agree in width with Manson's average. A new species of uncinaria, called *U. americana*, parasitic in man, was described in 1902 by Stiles, and is now made into a new genus called *necator*. It hails from the same neighbourhood as *U. duodenalis*, and does a fearful amount of mischief especially to children, causing great retardation of development, anæmia, and cachexia. The specimens shown, however, seem to be the ordinary *U. duodenalis*. In Europe the worm chiefly attacks miners, and attention was first called to it in connection with the boring of the St. Gothard tunnel in 1880, when it caused a serious outbreak of a "pernicious" anæmia amongst the workmen. It has recently occurred in England amongst the tin miners of Cornwall, and Boycott and Haldane have written two interesting papers about it in the *Journal of Hygiene*. It causes a marked eosinophilia. He also exhibited a small piece of duodenum showing exceedingly minute black spots, almost needing a lens to see them. These were the bites of the uncinaria, whose organs of attachment and piercing, four hooks and two teeth, are in the interior of a sort of "mouth capsule," and require patience and strong magnification in order to make them out.

Dr. O'Carroll read an interesting case of

SUFFOCATIVE HYDROTHORAX,

which will be found under the heading of "Clinical Records," page 120.

Dr. Martley instanced a case bearing some similarity to that described by Dr. O'Carroll.

SPECIMEN AFTER TALMA-MORRISON OPERATION.

Dr. Moorhead exhibited a specimen of above. The patient, a girl, æt. 22, was admitted to hospital in April last suffering from ascites, which had developed in a couple of days. After tapping, an operation was decided upon. The liver was found to be enlarged, firm, and hard. The surface was scraped, and the great omentum was stitched to the abdominal wall. After the operation the patient was tapped at intervals of ten days, 200 ounces of ordinary ascitic fluid being got. About two months ago she began to lose weight. It was decided to see what could be done to establish a permanent drain to the peritoneum, but no improvement took place, and the patient afterwards died. The interest of the specimen was in showing the results of a Talma-Morrison operation six months after its performance. On making the autopsy he found adhesions across the anterior abdominal wall, and along these could be seen the development of new veins, chiefly between the two peritoneal surfaces. There was no engorgement of the deeper vessels. The ones that had increased in size or number were the superficial ones. So far as concerned what they had hoped to do the operation was successful—*i.e.*, new collateral channels had been established. That it was not more so was probably due to the fact that the patient, in addition to cirrhosis, had a nutmeg liver. At the *post-mortem* they found no valvular lesions to account for their first idea that the heart might be partly the cause of the ascites, but the right ventricle was intensely fattily degenerated. In most cases of cirrhosis some alcoholic history could be obtained. This patient, however, had been a teetotaler all her life, but on inquiry he found that part of her occupation was the putting of photographer's negatives into methylated spirits, which might have something to say to the case.

Dr. Wheeler instanced a case in which, after finding an enlarged liver roughened on the surface, he performed a Talma-Morrison operation. That was two years ago. The patient was tapped once after the operation, but never since. He has been extremely well, and has gained three or four stones in weight. The other day he came to show himself; no tapping was required, but on examination the urine showed a good deal of albumen, giving signs of a cirrhosis of the kidneys. Ninety per cent. of cases in which there were no complications had been cured of ascites by the Talma-Morrison operation.

Dr. Earl said he had been struck with the fact that an alcoholic history was out of the question in many cases of cirrhosis—such as cirrhosis occurring in children. A great number of the patients met with in hospital practice drank all they could get, and if there was any intimate connection between alcoholic indulgence and cirrhosis of the liver, it should be one of the commonest affections, which it was not by any means.

The Chairman thought it hardly possible to be sure of the histological condition of the liver through such an incision as is made in most laparotomies. Outside inspection of the liver did not show the condition of the inside or of the capsule. He was therefore somewhat sceptical when he heard the liver accurately described on the basis of an incision for a Talma-Morrison operation, and he was not sure that the evidence did not indicate that the ascites would have disappeared eventually without any operation.

Dr. Farnan and Dr. Gunn also spoke, and Dr. Moorhead replied.

TRAUMATIC RUPTURE OF HEART.

Dr. Wheeler showed a ruptured heart. The case was that of a young actor, who was killed by a motor-car in August. The heart was absolutely torn in two.

THE SOCIETY FOR THE STUDY OF DISEASE IN CHILDREN.

Meeting held January 8th, 1907.

Mr. G. Pernet in the Chair.

A paper was read by Dr. G. D. Hawthorn entitled

PROTECTION OF RHEUMATIC CHILDREN.

Could anything be done to prevent or limit the occurrence of cardiac disease in children who are known to be liable to such disease as a result of a rheumatic inheritance or proclivity. Irreparable damage was frequently inflicted on the cardiac tissues by the rheumatic poison almost or altogether apart from incidents popularly recognised as rheumatic. The disproportionate frequency of heart disease in children may be due to the absence of arthritis in them, causing the patient not to be kept at rest for a sufficient time. It is necessary to educate the public as to the value of rest, and when this is done there may be some diminution in the incidence of heart disease in young subjects with its results of diminished usefulness of the individual.

Dr. Porter Parkinson fully agreed with the writer of the paper as to the value of rest in such cases, but till the profession were unanimous he was afraid there was little chance of it being enforced.

Dr. Ewart considered it was chiefly a matter of toxines and of individual resistance.

The Chairman pointed out that there were a variety of toxic conditions in children which gave rise to pains in the joints and muscles which had no relation to rheumatism. He doubted the existence of rheumatic inheritance.

A case of *Volvulus of the Small Intestine round a Caseous Mesenteric Gland* was read by Mr. Lockhart Mummery. It occurred in a boy, æt. 7, with symptoms resembling appendicitis. Operation showed a complicated volvulus of the ilium close to the cæcum; it was gangrenous, and on the point of giving way at several places. This was resected and the cut ends united with a Murphy's button. The case resembled appendicitis, the classical symptoms of acute obstruction of the small intestine being not at all prominent. Vomiting was a marked feature early, but had ceased when the child came to the hospital, and was never fæcal in character. There was no distension of the abdomen.

Mr. Jaffrey recorded a similar case in an adult, but had never seen it in a child. He discussed the difficulty of diagnosis.

Mr. Skelding had seen many such cases, and thought many cases of mild obstruction might be due to enlarged mesenteric glands.

A case of *Dilatation of the Stomach* of doubtful causation in a boy, æt. 12, and a patient showing the result of an operation for extreme depression of the frontal bone, were shown by Dr. C. O. Hawthorne.

A case of *Diabetes Insipidus* was shown by Dr. Cautley. The patient was a girl, æt. 9 years, who had had nocturnal enuresis for two years and enuresis diurna as well for six moths, with much thirst and excessive appetite. The urine varied from 46 to 262 ounces a day, was pale, acid, 1005 sp. gr., and contained 0.5 to 0.9 per cent. of urea. Adrenalin and atropin had effected no improvement, but valerianate of iron and quinine, with strychnine were more successful, the polyuria and thirst diminishing, and the patient gaining weight. There was no exciting cause discovered, and there was no sign of chronic interstitial nephritis.

Dr. Sutherland considered such cases were probably of neurotic origin.

Dr. Parker Weber called attention to the theory that diabetes insipidus was due to inability of the kidney to excrete salts in the normal way.

Dr. Clutterbuck had observed a similar case in which iron and ergot effected considerable improvement.

A case of *Premature Development* in a child, æt. 2½, was shown by Dr. Poynton. The remarkable growth began at a year old, when pubic hairs and sexual development were noted. The weight is now 3 stones 1 pound. Circumference of head 20 inches, of thorax 20½, of abdomen 23 inches. Length of the whole arm is 12 inches, and of leg 17 inches. The voice is deep, and memory good. Aspect rather suggests acromegaly. There is no suprarenal tumour to be felt. The parents are small and healthy.

A case of *Friedreich's Disease* in a girl, æt. 9, was also shown by Dr. Poynton. Five years ago she had measles, with severe cerebral symptoms, and had not been well since. She had now well-marked ataxy of legs and inco-ordination, with tremor of hands. Doubtful nystagmus. Knee-jerks abolished. Right plantar reflex extensor, but the left is flexor in type. Some lordosis of upper dorsal spine; double pes cavus; speech slow; no optic changes.

Œdema in an Infant was shown by Dr. Geo. Carpenter. It was 14 months old, and weighed 7 pounds. The œdema affected the face and limbs, and followed an attack of diarrhœa. The child was anæmic and the temperature subnormal. The urine contained no albumen.

A case of *Webbed Penis* was shown by Mr. Lockhart Mummery. The penis was enclosed within the skin of the scrotum right up to the tip; there was no other abnormality, and no history of similar defects in the family.

A case of *Congenital Cerebellar Ataxy* was shown by Dr. Sutherland. The boy, æt. 3, had suffered from general ataxy for eighteen months. He was healthy at birth, but had convulsions when six months old. At two years he was unable to sit or stand unsupported, and the limbs were tremulous and ataxic. The speech and intelligence were very backward. The knee-jerks were very active. There was double internal squint, and the optic discs were pale, but not definitely atrophic. The condition has remained the same for the past nine months, except that the child can now sit unsupported.

Dr. Sutherland thought it probable that the case was one of birth palsy following meningeal hæmorrhage, and probably involving the cerebellum.

A case of *Congenital Deformities of the So-called Mongolian Type of Amentia* was shown by Dr. Sutherland. The girl, æt. 8, showed the shortening and incurving of the little fingers and the oblique palpebral tissues so characteristic of the Mongolian type of imbecility; but this patient was perfectly intelligent, and had no cranial deformities. She was under treatment for fibroid phthisis.

LIVERPOOL MEDICAL INSTITUTION.

Meeting held Thursday, January 17th, 1907.

The President, Frank T. Paul, in the Chair.

ACUTE HÆMORRHAGIC PANCREATITIS.

Mr. W. Thelwall Thomas read a short note on three cases of acute pancreatitis, operated upon, with two recoveries. The first case, female, æt. 56, was *in extremis* thirty-five hours after the onset of acute abdominal pain with vomiting, quickly becoming fæcal. On incision, under eucaine, blood-stained effusion escaped from the abdomen, and the omentum was in a condition of fat-necrosis. The patient succumbed a few hours later. *Post mortem*, hæmorrhagic pancreatitis was found. The second case occurred in a girl, æt. 21, in whom the symptoms resembled perforation of a gastric ulcer, but with temperature. The condition became rapidly worse, and on operation fat-necrosis of the omentum was found with copious effusion of blood-stained material into the peritoneal cavity. The lesser peritoneal sac was drained by a loin drain and an anterior tube, as well as a tube into the pelvis. Thirty-five gall-stones were removed from the gall-bladder, and the latter drained. The pancreas was much enlarged without hæmorrhages. The patient made an uneventful recovery. The third case occurring was that of a man, æt. 40. The onset was acute, and a diagnosis of intestinal obstruction was made. The temperature rose, there was slight vomiting, and the abdomen became rigid and tender. On incision, thirty-six hours after onset, fatty necrosis in the extra-peritoneal tissue, omentum, and mesentery, was found. The gall-bladder, which was full of inspissated bile and the peritoneal sac were drained as in the previous case. The pancreas, which was very much enlarged and hæmorrhagic, was incised. The patient made a good recovery, but with a pancreatic fistula which remained open for six weeks. Mr. Thomas then discussed the etiology and treatment of the disease.

The cases were discussed by Mr. R. W. Murray, Dr. Stansfield, and Dr. A. G. Gullan.

THE ETIOLOGY OF INGUINAL AND FEMORAL HERNIA.

Mr. R. W. Murray read a note on the etiology of inguinal and femoral hernia, based on a series of *post-mortem* observations made upon 200 persons in whom, during life, there was no evidence or history of hernia. Among the 200 bodies examined, 68 peritoneal diverticula were found, 52 in the femoral and 13 in the inguinal region. Arguments were advanced in favour of the saccular theory of hernia, and Mr. Murray contended that all the evidence we at present possess was in favour of the belief that a pre-formed sac is the essential cause of inguinal and femoral hernia at all periods of life.

Dr. T. R. Bradshaw said that granting that an oblique hernia came down the inguinal canal, a direct inguinal hernia could not have such an origin. One important clinical fact made it difficult for him to accept the view that the tunica vaginalis was frequently found communicating with the peritoneum in persons who were not the subjects of herniæ, viz., the extreme rarity with which the fluid of ascites was found in the tunica vaginalis. He had only once seen such a case, more than twenty years ago, and in that case the fluid could easily be made to pass from the tunica vaginalis into the abdomen, or *vice versa*, by changing the patient's position.

Mr. Murray's paper was also discussed by the President, Mr. F. C. Larkin, and Mr. K. W. Monserrat.

VENTRO-FIXATION OF THE UTERUS.

Dr. H. Briggs read a paper on the above subject, of which an abstract will be found on page 116.

In the discussion following,

Dr. T. B. Grimsdale thought that the title of the paper was singularly unhappy, as it exaggerated the importance of the backward displacement of the uterus, and seemed to imply that all the symptoms were due to the backward position of the uterus, whereas all of the cases referred to showed other pathological conditions which were in all probability responsible for the symptoms present, the backward displacement being merely an incident in the case. As to the operation of ventro-fixation itself, it was safe and effective if properly performed, though the holding capacity of the bladder seemed to be slightly diminished by it.

Dr. W. Blair Bell thought that the pathology of retroversion and retroflexion was not always the same. He had applied his own views to Dr. Briggs' statistics and found there much to support them. For instance, he found that of the total failures 75 per cent. were in single women, and, further, that of the cases, whether single or married, complaining of menorrhagia, 85 per cent. were completely cured, while only 62 per cent. of the total number of cases were cured. These facts he considered important, as were some others to be deduced from the figures. He (Dr. Blair Bell) thought all forms of ventro-fixation unsurgical and dangerous, particularly the operation of peritoneal attachment described. He much preferred Gillian's operation, which he had now performed in a modified form for over a year ; or one of his own, first performed in March last, in which a loop of round ligament on each side was brought through the broad ligament and fixed behind the uterus—an operation which had been recently independently described.

Dr. Arthur Wallace remarked that ventro-fixation was not a scientific procedure, but in default of a better it was satisfactory in that it relieved the patient. The principal drawback was that between the utero-parietal attachment, the abdominal parietes, and the bladder there existed a potential opening or tunnel through which a loop of intestine might pass and become strangulated. A perfect procedure should bring about the formation of a complete peritoneal septum between the uterus, bladder, and abdominal wall. When the direct utero-parietal attachment stretched a little, as it appeared to do usually, there would result a kind of anterior mesometrium dividing the utero-vesical pouch into two halves, without any opening through which intestine might pass.

CORRESPONDENCE

FROM OUR SPECIAL CORRESPONDENTS ABROAD.

FRANCE.

Paris, Jan. 27th, 1907.

Treatment of Heart Disease.

The heart can be weakened from three causes—troubles of the innervation of the heart, of lesions of the cardiac muscles, and from obstacles of the periphery. The two first causes are the most important, the third is the consequence of the two first. A healthy heart, says Professor Huchard, one of the greatest authorities on cardiac disease, is generally uninfluenced by an obstacle ; it is only when the nerve centres are touched or that the muscle is somewhat degenerated, that its resistance commences to yield.

The influence of the nervous system on the heart was fully described by Cyon two years ago, and confirmed by clinical observations.

An agreeable emotion is sometimes sufficient to set right a heart that had begun to vaccilate. A quiet life, a comforting word, agreeable impressions, can go far in strengthening a weak heart. The moral action of a medical attendant has a very salutary effect on patients with heart disease.

Depressing emotions or violence diminishes considerably, on the other hand, the vital energy. Instead of being affected by moral emotions, the cardiac nerves may be irritated by certain toxic substances—tobacco, alcohol, or infectious maladies. Among the first might be ranked asystole following attacks of tachycardia. Here digitalin is indicated when signs of cardiac insufficiency, mitral souffle, venous pulse of the jugulars, big liver, &c., make their appearance, the use of digitalin in small doses producing a sedative action much appreciated by the patient. During four or five days ten drops of the solution cf digitalin (1—1,000) might be given, or a pill containing $^1/_{200}$ gr. each day for four days, and renewed every fortnight, braces up the heart.

The same cardiac irregularity is met with in exophthalmic goitre, and is due to some trouble of the thyroid secretion. Here also the same treatment will be found beneficial, but the malady can be generally avoided by treating the cause. Faradic currents, one electrode on the back of the neck, the other onthe goitre, ten minutes each day and continued for a year, and the internal administration of quinine, remove all danger from the heart.

The treatment of cardiac asystole varies as to the cause and the importance of the lesions. In acute infectious affections, the application of the ice-bag to the heart, injections of camphorated oil, caffein, spartein, or strychnine constitute the best treatment.

Besides these acute maladies, two groups of cardiac affections may exist. In the first, the valves are taken and subsequently the muscle; the second comprises the group of chronic myocarditis and arterial disease. Here the contrary obtains; the muscle yields first, and valves follow, and although both the mitral and aortic valves may be affected in the first group, it is the aortic valve that is especially diseased in the second. The treatment is different, for the myocardium is but little altered in valvular disease, while it is absolutely degenerated in aortic lesions. Consequently, large doses of digitalis might be given in the former, and very small doses or perhaps none at all in the latter.

In mitral disease, at the outset Professor Huchard recommends the following treatment:

Rest, because rest is the digitalis of the heart; milk or vegetable diet from which chloride of sodium should be excluded as much as possible. The second or third day a brisk purgative (scammony or jalap), and wet cupping over the liver to deplete the venous system. Bloodletting might be practised if the patient was cyanosed. The day after the purgative, and for *one day*, 50 drops of the solution of digitalin in one dose, or perhaps better, 20 drops the first day, 10 drops for three successive days, after which the patient is allowed to rest for fifteen days. At the end of that time, the remedy might be ordered again at the dose of 10 drops for four days so as to maintain a cardio-tonic action.

During the periods of suspension, strophanthus or spartein might be given more to content the patient than with a view of replacing the digitalin, as their effect on the heart is problematic.

Chronic myocarditis and arterial disease affect generally persons of advanced age where the cardiac muscle is profoundly altered. Wet cupping over the liver and even the heart is useful. In certain cases of incurable dilatation of the cardiac cavities, M. Huchard derived great benefit from wet cupping over the heart practised every day for a week. A milk regimen is ordered as in the previous case, but the patients would do well not to exceed a quart and a half of any liquid during the day. Diuresis by reduction of liquids is an important clinical fact which should be borne in mind. Digitalin in five-drop doses of the solution once a day and continued for ten or fifteen days, followed by suspension for five, ten, or fifteen days, will regularise the rhythm of the heart, give amplitude to the pulse, and reduce the bruit de galop.

These results are especially favourable when the digitalin is given concurrently with theobromin, which is the best of our diuretics and a first-class dechloriding agent. Patients formerly condemned by brutal treatment of large doses of digitalis, thanks to the employment of very small doses of digitalin combined with theobromin, can live and return to their occupations for years. The theobromin may be given in ten-grain doses morning and evening before meals, and continued for months.

When the asystole is of peripheric origin, the obstacle may be found in hard œdema of the lower limbs or a certain degree of embonpoint of the individual. The œdema will disappear by acupuncture, and an appropriate *regime* will decrease the obesity and thus relieve the heart.

As prophylatic treatment, small doses of digitalin should be given during the first ten days of every month.

GERMANY.

Berlin, Jan 27th. 1907.

At the Verein für Innere Medizin, Hr. Ism. Boas related a case of

SPONTANEOUS EXPULSION OF AN INTESTINAL LIPOMA.

A man, æt. 55, consulted him in October last on account of recurrent violent abdominal pain. The patient had travelled in South-West Africa shortly before; he there had malaria, and on his return had had a sharp attack of blackwater fever. He was not emaciated, but was so much incommoded generally by his pains that he was unable properly to fulfil his duties as member of Parliament. On examination, a swelling of the liver was found, which the speaker attributed to his malaria. There was no splenic enlargement, and examination per rectum was negative. A Carlsbad course of treatment was recommended, and this was carried out in the neighbourhood of Berlin. A fortnight later a letter was received from the patient, in which it was stated that he had been made worse by the treatment rather than better, and that the general condition had got distinctly worse. Then one day, when the pain was very bad, he felt as if something had given way, and shortly afterwards a tumour was passed per rectum. The tumour was the size of a couple of walnuts, and proved to be a lipoma.

These tumours were great rarities; up to the present only forty-five of the kind were known. The spontaneous expulsion of such a tumour was a still greater rarity, and only six other cases were known. The tumours were generally situated in the colon, rarely in the small intestine, and two distinct forms could be differentiated: (1) Such as grew from the surface of the bowel towards the abdominal cavity (two such cases had been described by Virchow in his work on tumours); (2) such as sprang from the submucosa and grew into the lumen of the intestine; they might attain a tolerably large size. The latter form mostly gave rise to invaginations and obstructions. In this case the tumour had a pedicle, and this was torn through, the patient suffering severe pain. The Carlsbad treatment, by increasing the peristalsis, had contributed to this event. (The tumour was shown.)

Hr. Wohlgemuth discussed

EXAMINATION OF A MAN WITH FISTULA OF THE PANCREAS.

He said that but little was known about the activity of the pancreatic gland during digestion in the human subject, whilst Pawlow's studies in respect to such fistulæ in the dog had given accurate data. Similar investigations had been made by Plessner and Ellinger. In both of the patients made use of for the investigation, however, the secretion of pancreatic juice was so irregular that the authors named could draw no satisfactory conclusions. The activity of pancreatic juice depended, as was known, on its three digestive ferments: the proteolytic (albumen digesting), lipase (fat digesting), and diastase (carbohydrate digesting). Lipase was not all active, but the inactive portion was rendered active by the accession of bile. The proteolytic ferment was made active by intestinal secretion and by bile, and according to the speaker's own investigation, also by expressed juice of the liver and aminic acid. The question whether pancreatic juice contains a ferment capable of coagulating milk he could answer in the affirmative, but this was only the case after stimulation.

He had carried out the following inquiries on a patient with a pancreatic fistula sent to him by Karewski. He gave the patient a fixed quantity of food from the groups of carbohydrates, albumens and fats, and from hour to hour collected the pancreatic juice. From this it appeared that the quantity secreted was greatest with carbohydrates, smaller with albumen, and smallest with fats. The secretion was most active in the second hour usually. According to Pawlow's experiments, the pancreas always acted as if with an aim—*i.e.*, the special secretion was according to the particular kind of food. Thus, when food rich in albumen was given, the proteolytic ferment was in greatest quantity, &c. This held good in the speaker's case also.

He also tried the effect of hydrochloric acid, and found that the pancreatic secretion was heightened by it.

From the results observed it was intended to reduce the secretion as much as possible by giving an anti-diabetic diet—free albumen and fat, with as little carbohydrates as possible. The diminution of the secretion was also aided by sod. bicarb.

Hr. Karewski observed that fistulæ of the pancreas were very difficult to treat successfully. In the case before them, a boy, æt. 16, had got his fistula from being crushed by being run over. He had lost as much as 400 ccm. of pancreatic juice through the opening, and had lost seriously in weight, and the greatest care in feeding did not compensate for the loss. Gradual contraction of the orifice had been attained by the diet suggested by Wohlgemuth. After removal of the drain after eight weeks the condition was tolerable, and the concentrated secretion reaching the stomach sufficed for digestion and even for restoring the body weight.

Hr. Biekel remarked that the manner of secretion described by Wohlgemuth corresponded to that given by Pawlow as regarded the dog. It might be assumed therefore that the other results obtained were also applicable to the human subject.

Hr. Fulda, said that the measurement of the digestion of albumen by the proteolytic ferment after the method of Metzschen was not accurate. He asked, further, how hydrochloric acid acted on the pancreatic secretion.

Hr. Wohlgemuth, in reply, agreed with Fulda's remarks, and then said that hydrochloric acid acted in the first place reflexly, and in the second by exciting secretion from the duodenum. The two actions were, however, separate and distinct.

AUSTRIA.

Vienna, Jan. 27th, 1907.

Ulcerative Endocarditis.

Zemann showed the heart of a young man, æt. 19, who died from acute ulcerative endocarditis in which was also present a cicatrised stenosis of the left conus arteriosus. The stenosis he considered was the primary cause of the ulceration of the endocardium, and appeared to him to be of a congenital nature.

Sternberg gave a short clinical history of the heart during life, which he took from the journals: Over the manubrium sterni about the level of the second rib, as well as the left intercostal space, a loud whirring sound could be both heard and felt, which could not be localised to the ostium cardii. The apex beat was felt between the fifth and sixth intercostal space outside the mammary line. In auscultation there was a rough protracted systolic murmur, while the second sound was scarcely audible.

About this time the patient had a rigor followed with remitting fever, enlarged spleen, and a great number of polynuclear leucocytes. At this stage of the disease septic endocarditis was diagnosed at the base, which was suspected to be congenital in origin. Sternberg thinks that Kurt's method of palpating the heart is the best for diagnosing these cases, the use of which he thinks is far too seldom practised.

Broncho-Stenosis.

Weinberger exhibited an anatomical preparation which he preserved from a case brought before the society three months ago, where there was left-sided broncho-stenosis caused by an aneurysm on the aorta, which displaced the heart and mediastinum into the left side of the thorax. The *post-mortem* confirmed the diagnosis arrived at then, viz., chronic endarteritis of a syphilitic nature in the ascending and arch of the aorta, where a large aneurysmal sac pressed on the isthmus of the aorta, also compressing the recurrent nerve, pulmonary artery, and bronchus of the left side. It was further shown that the displacement of the bronchus was the cause of the heart and mediastinum being so far set out of place, which could not be demonstrated with the Röntgen rays, and led to speculation during life. Hofbauer reminded the members of a similar case of displacement of the heart into the abdominal region from simple pleuritis. He thought this case of Weinberger demonstrated clearly how far the heart can be displaced by morbid changes. He would also like to draw their attention to another form of these respiratory excursions of the heart and mediastinum where no difficulty is experienced in breathing from broncho-stenosis although the displacement is as great as shown in cases that Holznetz and himself had exhibited at former meetings. Schrötter confirmed this opinion by cases he had also shown.

Gangrene of the Extremities.

Foltanek showed a child, æt. 3 weeks, with gangrene of the right foot, which he considered to be of an embolic nature, but refused to offer any opinion of the primary cause of the embolism. Escherich showed a cast of another similar case in a young child, but was unable to throw any light on the origin of the disease

Hochsinger remembered meeting with a similar condition in a new-born child four years ago, a description of which he published at the time. The necrosis seemed to point to some interference in the thoracic artery which was confirmed in the *post-mortem* room by an embolus firmly impacted in the long thoracic artery.

Recurring Parotitis.

Reuss recorded the history of a girl, æt. 5½ years, with a chronic recurring enlargement of the parotid gland, which commenced when she was æt. 2. The unusual character is its disappearance in the summer, but immediately winter sets in the gland enlarges with hard marble-like swellings over the surface, but without pain. No other morbid changes are present.

Kummel is the only one in our literature who describes a similar condition in an adult.

FROM OUR SPECIAL CORRESPONDENTS AT HOME.

SCOTLAND.

Death of the Oldest Practitioner in Scotland.—The late Dr. Alexander Peddie, Edinburgh, whose death was alluded to last week, was born in 1810, and had thus reached the great age of 96. During his long life he had witnessed many changes, and played his part in many of them. His contributions to medical science are for the most part more than half a century old, and though forgotten by many at the present day, they and his other work commanded the respect and attention of his contemporaries. In 1854 he advocated the view that inebriety should be considered as a manifestation of a form of insanity, and his paper on the subject "The Pathology of Delirium Tremens and its Treatment without Stimulants or Opiates" constituted a considerable advance on the practice of the time. He was a recognised authority on this and cognate subjects, and in 1872 gave evidence before Parliamentary and departmental enquiries on the treatment of habitual drunkenness. Dr. Peddie was in active practice in Edinburgh until about fifteen years ago. He began his career by being apprenticed to Syme, then conducting his own hospital and surgical school at Minto House. Dr. John Brown, the author of "Rab and His Friends," was third on the list of apprentices, Dr. Peddie was thirteenth. A life-long friendship was struck up between the two lads, and Peddie became known to a wider public as the biographer of John Brown than as the author of professional treatises. Apart from his professional abilities, he was one of the best-known among Edinburgh citizens and having spent all his days in his native town he was a link between the society of to-day and that of our grandfathers.

The Compulsory Notification of Phthisis.—The Leith Town Council are promoting a Provisional Order, in which there is a clause relating to the compulsory notification of phthisis. The Local Government Board take exception to this, as a retrograde step, and express the opinion that local authorities ought not to promote local acts when the powers they desire are contained in general statutes. The Local Government Board contend that the clause in question is not necessary, being incorporated in the Public Health and Notification Acts. Special provisions already exist for the extension of the Notification Act to diseases other than therein specified, including pulmonary tuberculosis. The action of the Local Government Board in this matter is not without interest, because it was strongly urged by some at the recent discussion on the compulsory notification of phthisis in Edinburgh that the proper course for the city to adopt was to act by Provisional Order, not, as was alternately decided on, by an extension of the existing Statute.

Proposed Memorial to the late Dr. Finlayson.—At a largely attended meeting held in Glasgow on January 24th, it was unanimously decided to form a lectureship on medicine and cognate subjects, to be called the Finlayson Memorial Lectureship. In this way it would be possible to bring original workers and men of distinction from other places to give the practitioners in the West of Scotland an account of their researches. An executive committee was formed with Sir Hector Cameron as convener, Dr. Gourlay as treasurer, and Drs. Duncan, Macfarlane, and Freeland Fergus as honorary secretaries.

British Medical Association, Scottish Branch. The members of the Edinburgh Southern division held their first annual dinner on January 19th. Among those present were Dr. Norman Walker, the direct representative on the General Medical Council. In replying to the toast of the Magistrates and Corporation, Councillor Cullen, M.D., said that in the administration of the notification of phthisis the Town Council would never apply the drastic clauses of the 1897 Act, if the public did not wish it; they would always study the opinion of the medical profession on these matters. A very pleasant evening was spent by the members. The tendency to develop the social side of membership of the British Medical Association is growing somewhat, and this seems one of the best ways in which that body can promote the solidarity of the profession.

Action against Dr. Adam, of Forres.—An action has been entered in the Elgin Sheriff Court at the instance of William Kessack, of the town of Forres, against Dr. Adam, for damages in respect of his alleged illegal and unwarrantable action in making a *post mortem* examination on the remains of the wife of the pursuer. The pursuer prays the Court to ordain the defender to pay to the pursuer the sum of £50, with interest and expenses for loss, injury, and damage to his feelings. Dr. Adam denies the relevancy and conclusions drawn therefrom.

BELFAST.

Death of Dr. J. C. McCleery.—One of the oldest medical men in Ulster died last week :—Dr. James C. McCleery, of Belfast, who had reached the good age of 83. He took the licence of the Royal College of Surgeons of Ireland in 1847, and at one time had a large and lucrative practice in Belfast, but about twenty years ago he retired from active practice, and since then has lived very quietly on the outskirts of the city, seldom or never taking part in any public affairs. He was genial and courteous with those who knew him, but reserved and retiring with most.

Derry Borough and County Infirmary.—The annual meeting of the Committee of Management of this Hospital was held last week, when the medical report was read by Dr. J. G. Cooke, the resident surgeon. The intern patients last year numbered 1,371, a daily average of over 50, the operations performed numbered 298, and anæsthetics were given 212 times. With the help of a ball, a bazaar, and a donation of £500 from the Hon. the Irish Society, the finances of the hospital are in a satisfactory state.

Cerebro-Spinal Meningitis. Following the death of a medical student from cerebro-spinal meningitis as reported in this column last week, there have been several other cases in the city. Twelve cases had been admitted to the Fever Hospital at Purdysburn up to Saturday, of which four had proved fatal, and several others appeared likely to do so. Besides these, at least five fatal cases had occurred outside the Fever Hospital. In one instance a family of five children were attacked within twelve hours of each other, and four died, indicating a degree of virulence hitherto unknown in this affection. Two of these last cases died at home after only a few hours' illness, and an inquest was held, at which Professor Symmers gave evidence, and the publication of this in the daily papers will no doubt tend to the discovery of other cases.

The Irish University Question.—Very deep interest has, of course, been aroused here by Mr. Bryce's statement regarding the Irish University question, just published, but no one cares to commit himself to a definite opinion till further details are forthcoming. To those who wished for an Ulster University, the scheme outlined by Mr. Bryce is, of course, a disappointment, for it is realised that a large national university is much less likely to split, or be split, into several local universities, than would be a reformed and enlarged Royal University from which Trinity College was excluded. If a liberal equipment is offered to Queen's College, Belfast, it will no doubt go a long way towards making the scheme acceptable in the North. The appearance of the promised Bill will be awaited with interest on all sides, more especially as there is a tendency to believe that it is pretty sure eventually to become law.

LETTERS TO THE EDITOR.

THE CASE OF EDALJI.

To the Editor of The Medical Press and Circular.

Sir,—Though not belonging to the medical profession, I ask space for a few remarks on the case of Edalji. A good deal has been made of the fact that no evidence of his defective sight was given at the trial. But there was no reason why it should have been given. The case for the prosecution was that Edalji killed the horse during a walk which he took on the evening of August 17th, and as his sight did not prevent him from taking this walk, it could hardly be alleged that it prevented him from killing a horse while taking it. Mr. Distoumal went so far in his opening speech as to say that Edalji wore the incriminating coat during this walk, although no evidence was given to that effect. Even in the examination of a policeman who saw the horse at 11 o'clock p.m., long after Edalji had returned from his walk, Mr. Distoumal elicited that the night was so dark that the horse might have been injured at the time without his perceiving it. It was only when the veterinary surgeon who saw the horse in the morning declared that the injury was too fresh to have been committed during the walk in question, and evidence was given that the prisoner had worn a coat of a different colour during the walk, that Mr. Distoumal fell back on the theory that Edalji had slipped out of the house during the night, which was very dark as well as wet, and committed the outrage. The condition of the prisoner's eyesight only became important in connection with this theory.

I do not believe that the writer of the anonymous letters had any connection with the outrages, none of which occurred while the letters were going on. But the writer was aware of the condition of the prisoner's eyesight. One of the letters stated that Edalji had killed a horse on April 11th *at full moon*. Why at full moon ? Plainly because he thought the prisoner would be able to disprove the charge if he had mentioned a dark night. As a matter of fact, no horse was killed at full moon that April, but one was killed when the moon was nearly full in the following May. The writer, whose knowledge of the outrages was of a vague and general kind, and whose only object was to incriminate Edalji, made a mistake in the date, and invented a gang to account for the outrages which occurred on dark nights. A curious circumstance, however, is that after Edalji's conviction an outrage, evidently belonging to the series, was committed almost at full moon. I mean that on Stanley's horses on the night of November 2nd.

I am, Sir, yours truly,
A Barrister.

CONGRESS OF CLIMATO-THERAPY AND HYGIENE.

To the Editor of The Medical Press and Circular.

Sir,—I should like to call attention to the fact that those who have never visited the Riviera will have an opportunity of doing so under very favourable circumstances during the coming Easter. The third French Congress of Climato-Therapy and Urban Hygiene will be held this year on the Mediterranean seaboard, It assembles at St. Raphael on April 1st (Easter Monday) and lasts for a week. Those who take part will have exceptional opportunities for seeing Cannes, Nice, Beaulieu, Monte Carlo, Mentone, and other well-known places. The programme also includes a trip to Corsica, with which it is proposed to wind up the proceedings. This, however, is an "extra" which will probably not appeal to those with whom time is an object. I shall be happy to supply any further information to those of your readers who are interested in the matter.

I am, Sir, yours truly,
Leonard Williams.
8, York Street, Portman Square, W.
January 23rd, 1907.

ABOUT UNTAXED ALCOHOL.

To the Editor of The Medical Press and Circular.

Sir,—The uses of alcohol in medicine are endless, but its employment for external application, in dermatology, etc., must be largely limited by the prohibitive price caused by the tax of 16s. per gallon.

The Continental practitioner orders it largely for bed sores and sprains, and a host of skin affections, because he enjoys the use of the article free of duty, whilst we must in similar cases use methylated spirits, which, containing 10 per cent. of wood naphtha as well as paraffin, is far too crude, irritating and unpleasant for effective administration.

The Revenue Authorities, impressed by the injustice done to the manufacture of fine chemicals in Britain by the alcohol tax, have recently allowed the use of pure spirit without paying duty, for scientific purposes, under the title of "Industrial Alcohol." As this is practically a pure 90 per cent. alcohol, it would do admirably for therapeutic external purposes; but, so far, the Revenue Authorities do not permit its use by doctors.

There is reason to believe that if a strong and united demand were made by medical practitioners for the use of Industrial Alcohol, for external purposes only, in the prescription of doctors, the Inland Revenue authorities would permit it under restrictions. This demand ought therefore to be made at once.

I am, Sir, yours truly,
J. C. McWalter, M.D.(Brux.), D.P.H.

CONTINENTAL HEALTH RESORTS.

To the Editor of The Medical Press and Circular.

Sir,—On page 99 of The Medical Press and Circular, January 23rd, 1907, your Continental correspondent has made some observations on the advantages of the Riviera coast in the winter months which for some reason seem to have been disregarded of late. Some years ago I spent a winter at Cannes, and for want of some interesting occupation, I gave up my time to looking into the questions which interest us when we are dealing with the value of any locality or country in its influence on disease. It was useful to me then to have some knowledge of geology, chemistry, and physics, for they helped me much in carrying out observations properly, and saved me from being misled by the interested and exaggerated statements which are so common when we are discussing the merits of a place in regard to invalids, and when there are interested motives sometimes for extolling the characters of such place. What impressed me greatly and what I have never forgotten was the extraordinary difference in the middle of November between the wretched state of London, when we left it, and the brilliant warmth and colour of that coast of the Mediterranean between Marseilles and Cannes. I remember well how on Christmas Day I found the sea was really warmer for a bath than I had ever found it in midsummer in England. Now the question of chief interest as we travel along that coast is the variation in the geology—that is, in the character of the earth or soil. On these depend chiefly the character of the atmosphere, its dryness or humidity, and it is easy to see how Hyeres, Cannes, Mentone, San Remo, and other places differ from one another, when we know the nature of the stratum on which they are located.

I will not venture, however, to intrude upon the patience of your readers by saying more than that the remarks of your Continental correspondent might have been much stronger than they are on the value of the Riviera to invalids and how heartily I agree with him, after having walked along that North Coast and down from Genoa along the Spezzian shore, in his opinion that comparison between our country and the Mediterranean in the winter season is simply ridiculous, and is evidence of something worse than ignorance.

I am, Sir, yours truly,
Robt. J. Lee, M.D.Cantab.
Pwllheli, North Wales, Jan. 27th.

OBITUARY.

CHARLES JAMES OLDHAM, F.RC.S.Eng., L.R.C.P.

A well-known member of the local medical profession died on the 24th inst, in the person of Mr. Charles James Oldham, of Hove, at the age of 60. He received his professional training at Guy's Hospital, where he held various resident appointments. He was a Member and eventually a Fellow of the Royal College of Surgeons (England), and was also L.R.C.P. (London) and L.S.A. He came to Hove in 1870, and enjoyed a large practice, more particularly by reason of his skill as an oculist. The Sussex Eye Hospital loses in him a honorary surgeon, and he was also consulting surgeon to the Brighton, Hove, and Preston Dental Hospital. Apart from his professional career, he devoted himself to music, and his enthusiasm for the art was notably demonstrated in the collecting of rare instruments. Among his treasures are five most valuable "Strads"—three violins, a viola, and a 'cello. For the last-named he paid a price which ran into four figures; and one violin and the viola formed part of the set of instruments which Stradivarius made for the King of Spain of the time. Another of the violins once belonged to Rode, a great violinist of his day. Mr. Oldham was a director of the Royal Academy of Music, and locally will be most widely remembered as the very active President of the Brighton Sacred Harmonic Society. The news of his death will be received with deep regret by all who enjoyed his friendship or acquaintance.

THOMAS GOWANS MACCORMACK, M.A., M.B.Edin.

We regret to record the death in the 17th instant, of Dr. Thomas MacCormack, of Newport. Deceased came to that town some twelve years ago, and took a prominent local position. He was a strong advocate of the open-air treatment of phthisis, and was at one time president of the Newport Medical Society. For many years he was honorary surgeon to the Outdoor Department of the Newport Hospital. He was educated medically at Edinburgh, where he graduated M.A., M.B. and C.M. in the year 1893.

SPECIAL ARTICLES.

ROYAL COMMISSION ON TRINITY COLLEGE, DUBLIN, AND THE UNIVERSITY OF DUBLIN.

THE final Report of this Commission was presented and published during the past week. It is a most important document, though in some respects its conclusions are too wanting in unanimity to enable a definite answer to the vexed Irish University Question to be obtained therefrom. In another place we comment editorially on the Report, and here we merely publish a *résumé* of those features which are of most interest to medical men.

The Commission sat on 21 days, and heard 44 oral witnesses, besides receiving a number of written statements from persons and bodies interested. In their Report the Commissioners commence by making a general statement of the present condition of Trinity College and of the University of Dublin. They then deal with the place which Trinity College and the University hold as organs of the higher education in Ireland, and inquire whether there are any steps proper to be taken to increase their usefulness to the country with reference to the claims of His Majesty's subjects of the Roman Catholic faith. They subsequently inquire into the other matters mentioned in the terms of reference, including the propriety of recommending changes in the institution for reasons disconnected with the religious question.

The Report concluded with a summary of the general conclusions and recommendations arrived at by the Commission. The following are the most important of these conclusions:—

1. That Trinity College has been and is a satisfactory organ for the higher education of the Protestant Episcopalian population of Ireland, but that it has never been, and is not now, to an extent adequate to the reasonable requirements of the country, an organ for the higher education of the Roman Catholic population.

2. That while the Commissioners are divided in opinion in regard to the merits of the various schemes proposed to them involving the creation of a new College in Dublin acceptable to Roman Catholics, they, with one exception, recommend the establishment of such a College in Dublin.

3. That it is impossible to recommend any such changes in the constitution of Trinity College as would render it acceptable to the Roman Catholic Episcopate.

4. That there shall be included in the Statute or Charter regulating the future constitution of Trinity College, express powers to make certain special arrangements for Roman Catholics, Presbyterians, Methodists, and other religious bodies.

5. That in the event of a new College being founded in the University of Dublin or in the Royal University, there shall be power to establish a system of intercollegiate co-operation between that College and Trinity College.

6. That the Board or Governing Body of Trinity College shall ultimately consist of not more than fifteen nor less than nine members, who shall be approximately divided as follows:—One-fourth to be the Provost and other *ex-officio* members; one-half to be elected by Fellows and Professors voting together, from among the Fellows; and the remaining fourth to be elected in the same way from among the Professors who are not Fellows; and that various standing and other committees shall be appointed for conducting the business of the College.

7. That the existing Council shall be abolished, and that in its place there shall be substituted an Academic Council and Boards of Studies; that the professors and lecturers in each Faculty shall constitute a Board of Studies for that Faculty; and that the chairmen and vice-chairmen of the several Boards of Studies, together with the Provost, shall constitute the Academic Council; that it shall be the duty of the Boards of Studies to report to the Academic Council on all matters pertaining to the Faculties; and that it shall be the duty of the Academic Council to report on these matters to the Governing Body.

8. That no change shall be made as to the constitution or powers of the Senate.

9. That ultimately the present distinction between Junior and Senior Fellows shall cease, and that the total incomes of the Fellows shall be arranged on a more equitably graduated system.

10. That it shall be permissible for a candidate at the ordinary annual fellowship examination to present for consideration any dissertation or published or unpublished work; that the Governing Body shall elect the candidate who in their judgment is best fitted for a Fellowship in the College, but it shall not be incumbent on them to make any election; that election shall be for three years, during which period the Fellow shall remain a Probationary Fellow, and that at the end of that period he shall be eligible for a full Fellowship without examination. That the tenure of a full Fellowship shall be until death, retirement, incapacity, or grave fault.

11. That a fixed number of Fellowships, terminable with the office, shall be assigned to Professors.

12. That the Governing Body shall have the power of electing, without examination, to an occasional Fellowship, any person whom they desire to employ in the educational service of the College.

13. That the whole body of Fellows shall have a power to make formal representations to the Governing Body about important questions of policy or administration.

14. That the scope of studies in Trinity College might with advantage be widened in many directions.

15. That the public examinations in Trinity College are too numerous.

16. That the appointment to each of the more important professorships shall be made by an electoral Board selected from without as well as from within the College, the minor chairs to be filled by election by the Governing Body after receiving the recommendations of the respective Boards of Studies; that the tenure of professorships shall be until death, retirement, incapacity, or grave fault.

17. That, as regards the Medical School, effect shall be given to the agreement embodied in the Joint Statement of the Board of Trinity College and the President and Fellows of the College of Physicians, as submitted to the Commission.

18. That encouragement shall be afforded to research, and that special courses for degrees for research shall be established.

19. That the Governing Body, with the assent of a majority of the Fellows, shall have the power to make ordinances for the government of the College, subject to certain conditions.

20. That no candidate shall be admitted to graduation unless after study for some specified period within the College, or an equivalent attendance at lectures given by teachers recognised by the University.

The foregoing is a brief summary of the more important recommendations of the Commission. Some of them possess no special interest as such for medical men, whilst others are of considerable interest, and therefore we reproduce those portions of the Report on which these more interesting conclusions are based. With reference to the step to be taken to increase the usefulness of the College and University with reference to the religious difficulty, the Commissioners report as follows:—

"It will be convenient to state at once the principal schemes which have been suggested to us for the solution of the religious difficulty. They are:—

i. Such a modification of the constitution of Trinity College as shall make it satisfy the claims of the Roman Catholic Hierarchy.

ii. The establishment in the University of Dublin of a College which, whilst imposing no tests on the students or professors, shall yet be so constituted as to satisfy the Roman Catholic Episcopate that it created no danger to the faith or morals of the Roman Catholic students.

iii. The establishment within the University of Dublin of three or perhaps four addtional residential Colleges, namely, the Queen's Colleges at Belfast, Cork, and perhaps that at Galway, and a new College suitably equipped in Dublin without tests but intended to give adequate security against danger to the faith and morals of the Roman Catholic students.

iv. The establishment of a new University acceptable to Roman Catholics and with a similar constitution as to tests and the security of faith and morals, with or without the establishment of another University in Belfast.

v. The establishment in the Royal University reformed on the lines indicated in the report of the Commission of 1901, of a duly equipped College with the absence of all tests, but with the needful security as to faith and morals.

"We are unanimously of opinion that it is impossible to recommend any such changes in the constitution of the College as would render it acceptable to the Roman Catholic Episcopate. Inasmuch as the Standing Committee of the Roman Catholic Bishops in the document sent by them to us have assured us that the Catholics of Ireland "would on no account accept any scheme of mixed education in Trinity College, Dublin," we cannot hope to render the College acceptable to the Roman Catholic Episcopate by reasonable changes in its constitution. In the above conclusion the Commission are unanimous. The Bishops, in the document before mentioned have in fact disclaimed any desire on the part of the Roman Catholic people to have changes made in the constitution of the College for their sakes. Meanwhile there is a considerable body of Roman Catholic laymen in Ireland who would gladly send their sons to Trinity College if they could do so with the approbation of their Church; and their views have been presented to us in evidence.

"In particular we have very carefully considered certain proposals made by a group of Fellows and Professors in the hope of rendering the College more acceptable to Roman Catholics, but whilst we recognise the liberal and generous spirit which prompted the attempt, we are bound to say that at the present moment we cannot hope for a solution on these lines. We nevertheless think that it would be desirable that the College should continue to hold out the welcome which it extended by the resolutions of the Board of November, 1903, and that it should do so even more emphatically than it has already done; and for that purpose we *recommend* that there shall be included in the Statute or Charter regulating the future constitution of the College, express powers at any time to carry into effect the proposals made by the resolutions referred to, and to extend these or similar offers to the Methodists and other religious bodies in Ireland in addition to the Roman Catholics and Presbyterians; and also to make any arrangements which may render the College more acceptable to members of the Roman Catholic Faith who desire to enter within its walls.

"Many, or perhaps all, of these things may be within the powers of the College without further authorisation; but our suggestion is that the powers should be expressed in the constituent Charter or Statute by way of a permanent offer, of which, in the future, advantage may possibly be taken.

"On another point we are in practical agreement. Whatever may be said for or against the creation of a new University in Dublin acceptable to Roman Catholics, yet looking at the question as a practical one, we have the greatest doubts whether the creation of such a University would at present be feasible.

"If we thus lay aside the schemes for the entire modification of Trinity College and for the erection of a new University, we come to consider the creation of a new College and the three schemes which have that feature in common, and here we are not in agreement. Of the Commissioners, four (the Lord Chief Baron, Sir Thomas Raleigh, Dr. Douglas Hyde, and Dr. Coffey) are of opinion that the University of Dublin should be remodelled so as to contain five Colleges within it, viz., Trinity College, a College acceptable to Roman Catholic students in Dublin, and the three Queen's Colleges; one of the Commissioners (Professor Jackson) thinks that such a reconstruction of the University of Dublin would be the only satisfactory solution; but in view of the hostility of the Colleges concerned, is not prepared to recommend an immediate attempt to realise the scheme; three (Sir Edward Fry, Sir Arthur W. Rücker, and Mr. Butcher) think that in the circumstances the reconstruction of the Royal University so as to become a teaching University comprising four constituent Colleges, viz., a new College in Dublin acceptable to Roman Catholics and the three Queen's Colleges, would be the best solution of the difficulty, and that therefore no additional College should be introduced into the University of Dublin; and one (Mr. Kelleher) is of opinion that no new College should be created. Four Commissioners are therefore in favour of remodelling the University by the admission of additional Colleges and four are against it, and one, though in favour of it, does not recommend immediate action."

With reference to the Medical School, the Commission reports as follows:—

"Amongst the Professors of the School of Medicine are four King's Professors of the practice of Medicine, of Materia Medica and Pharmacy, of the Institutes of Medicine, and of Midwifery, respectively. These Professors are elected, not by the Board of Trinity College, but by the President and Fellows of the Royal College of Physicians of Ireland, and they each receive the sum of £100, Irish, or £92 6s. 2d., English, from the income of the estate of Sir Patrick Dun, of which the College of Physicians are the trustees. The will of Sir Patrick Dun was proved in 1713, and the foundation thereby created has been the subject of legislation by the Statutes of the 15th George II. (Ireland), 1741; the 25th George III., cap. 42 (Ireland), 1785; the 31st George III., c. 35 (Ireland), 1791; the 40th George III., c. 84 (Ireland), 1800; the 25th Vic., cap. 15, 1862; and the 30th Vic., cap. 9, 1867. The present position of matters in relation to Sir Patrick Dun's foundation is shortly as follows:—The College of Physicians are still the trustees of Sir Patrick Dun's estate and the electors to the four King's professorships in Trinity College; a hospital known as Sir Patrick Dun's Hospital has been erected and is maintained and managed by a body of Governors, and in this hospital clinical instruction is given by a staff of medical teachers. The estate of Sir Patrick Dun may be estimated to produce £1,000 a year: out of that sum the four King's Professors in Trinity College receive yearly £369 4s. The salary of librarian and clerk and other minor matters absorb a sum of over £100 a year, leaving about £500, which is paid to the Governors of Sir Patrick Dun's Hospital.

"The connection thus existing between these bodies—viz., Trinity College, the College of Physicians, and the Governors and staff of Sir Patrick Dun's Hospital, all more or less directly interested in the same estate, has not always been found to work smoothly, and a desire has for some time past arisen for the severance of the tie. In November, 1906, an agreement was arrived at by the two Colleges and the Governors of the Hospital, the terms of which will be found in the joint statement of the two Colleges. Under this agreement, if sanctioned by Parliament, the right and duty of electing to the King's professorships will be transferred from the College of Physicians to Trinity College; one-half of the estate of Sir Patrick Dun will be transferred to the Governors of the Hospital, a sum which will yearly produce £200 Irish will be transferred to Trinity College, and the residue of the estate will remain in the hands of the College of Physicians.

"We think that it will be very beneficial to the College to obtain the right of electing to the four King's professorships, and we are of opinion that the compromise arrived at by the two Colleges is upon the whole a wise one. We therefore *recommend* that the agreement embodied in the joint statement shall receive parliamentary sanction, and that so far as is necessary the existing legislation relative to Sir Patrick Dun's foundation shall be repealed."

(*Résumé to be concluded in our next.*)

CORONER MAITLAND AND HIS COURT.

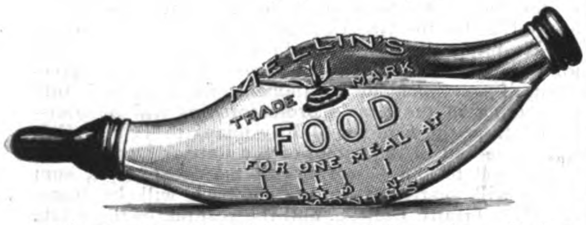
A resumed inquest was held on the 24th inst. at Normanton on the body of the illegitimate child of Annie Scruton, a single woman living at Bradford. The child was born at the home of a nurse at Southport, and died at Normanton Station on Christmas Day, seven days after its birth, as it was being conveyed to Bridlington by Mrs. Mary Ellen Robson, who had "adopted" it. The coroner, according to the newspaper report of the transactions, said the child's death was due to exposure caused by neglect." A witness stated that before the birth of the child arrangements had already been made for the "adoption" of the child *with a premium of* £10. In the report there is no evidence whatever that the child did die from exposure, and no evidence to prove that it did not die from poisoning. The coroner should have had proof before him that the death was not due to poison before he assumed that it was due to exposure, and to distribute censures in accordance with a bare assumption. The mere fact that £10 was given to the witness Robson to take charge of the infant permanently makes it look suspiciously like a baby farming case. How many children had Robson of her own, and how many had she "adopted" for £10 or for money at all before the present case? What more likely than that "something" was given to keep the infant quiet before its journey began, and that that something proved fatal? Was a *post-mortem* examination made with an analysis of the contents of the stomach? To talk of the child dying of exposure when "well wrapped up, fed, and well taken care of," as the doctor said, and carried in the woman's arms, getting warmth both from the arm around it and the body to which it was held, is nonsense; there must have been some other cause. Did the doctor express any opinions respecting the woman Robson? Whether he did or not, the coroner "entirely disagreed" with them.

As far as appearances go, the matter should not rest. There is a *prima facie* case for a further inquiry, not by the Society for the Protection of Children, but by the Home Secretary. The woman Robson has so far done well out of the transaction. She gets her money and has to give very little in return for it.

LABORATORY NOTES.

MELLIN'S FOOD—ITS ADMINISTRATION AND ITS COST.

Mellin's Food, like all other good things, is likely to fall into discredit unless used in the proper manner, and in order to do away with the gravest source of error in its administration, namely, the improper feeding-bottle, the firm have just brought out a special pattern which combines the best features of the latest bottles with some original ideas of their own. The bottle is roughly boat-shaped, with a rubber cork at one end and the teat at the other. It is so made that the bottle must be tilted up before the child can use it, and therefore milk and air cannot be sucked in together. At the far end of the bottle is a valve which prevents milk spilling, and only admits air when the milk is being sucked out. Of course, the whole bottle can be cleaned with the greatest facility. Messrs. Mellin, finding it persistently asserted that artificial foods are expensive, and that the cost of feeding a child with them is too much for the poor, have drawn up a leaflet, comparing the cost of feeding a child on Mellin's Food, combined with milk in due proportion, with that of feeding one on "municipal milk" alone. This shows that only in the third month do the figures approximate, the advantage up till then being decidedly in favour of Messrs. Mellin. They point out, moreover, that Mellin's Food not only enriches but also modifies cow's milk till it becomes closely analogous to human milk, whereas municipal milk is only modified by sterilisation and the addition of extra ingredients, such as lactose, salt, lime-water, or sugar.



NEW TABLOIDS.

A new "Tabloid," brought to our notice by Messrs. Burroughs and Wellcome, is "Xaxa," a name adopted to designate their preparation of acetyl-salicylic acid. This drug has already attained some reputation as a substitute for salicylic acid and its salts, and it is said to be equally effective with them in the treatment of gout, rheumatism, and allied affections, without possessing unpleasant after-effects. "Xaxa" contains no free salicylic acid, and beside the ordinary range of usefulness of the salicylates it has been found useful in neuralgia, glycosuria, and the pains of tabes.

We tried it in a recent case of influenza, in which the patient complained of severe pain in every joint. In this there was undoubtedly latent rheumatoid arthritis and the value of this tabloid was at once apparent.

Another useful "Tabloid" is Eucaine Lactate. It seems probable that the lactate will eventually supersede the hydrochloride in minor surgery, as it is readily soluble, non-irritating, and staple in solution.

A NEW PURGATIVE WATER.

Villacabras is a new purgative water, whose chief constitutent is sulphate of soda. It comes from the Chinchon district of Spain, and it is claimed that it does not possess so bitter a flavour as other waters. Owing to filtration according to the Pasteur system before bottling, the sulphureous smell which is the principal objection to waters of this class is eliminated, and the dose required is smaller than with the majority of purgative waters.

Medical News in Brief.

Annual Dinner of the British Gynæcological Society.

After some twenty-one years of existence, the British Gynæcological Society is about to merge its separate existence by amalgamating with the Obstetrical Society. This fact made the recent annual dinner on January 17th an occasion of unusual interest, as being probably the last to be held by the Society. The Chair was occupied by the President, Mr. F. Bowreman Jessett. Mr. Henry Morris, President of the Royal College of Surgeons, responded for that body to the toast proposed by Mr. W. D. Spanton. The toast of the Society was proposed by Dr. F. H. Champneys, who maintained there could be no serious opposition to the amalgamated societies. The Obstetrical Society was eloquently proposed by Dr. Macnaughton-Jones, and other able and interesting speeches were contributed by Dr. H. R. Spenser, Dr. Clement Godson, Director-General Ellis, R.N., Surgeon-General Sir Thomas Gallwey, A.M.S., and others. An excellent musical entertainment was provided, and the whole affair reflects great credit upon the honorary secretary, Mr. H. Overy.

Motor Omnibuses and Other Street Noises.

An influential deputation waited on Mr. Gladstone at the Home Office on Thursday last (among whom were several representative members of the medical profession), for the purpose of seeking an abatement of street noises in London and other large cities. The principal points put before the Home Secretary referred to (1) *Motor Omnibuses and Traction Engines.* The noise, speed, weight, smell, and danger from skidding and careless driving of these vehicles, and the absence of police powers to define routes and regulate the hours of running; the damage to property caused by vibration and the necessity of the police having power to proceed against offenders. (2) *Organs and Street Cries.* Mr. Gladstone stated in his reply that he fully admitted the desirability of abating the nuisances complained of, and promised that no effort should be spared to bring about the needed reform.

Royal College of Surgeons in Ireland.

The annual dinner of the Royal College of Surgeons was given on Saturday evening in the Examination Hall of the College, and was honoured by the presence of His Excellency the Lord Lieutenant. The Honorary Fellowship of the College was conferred on Mr. Priestley Smith, Professor of Ophthalmology in the University of Birmingham, before dinner. Amongst the after-dinner speakers were the Lord Lieutenant, the President, R.S.I., the President, R.C.P.I., Lord Grenfell, Commander of the Forces in Ireland, and the Attorney-General. We regret that owing to the pressure on our space, caused by the University Report, we are unable to notice the proceedings at greater length.

Action Regarding the Sale of a Medical Practice.

A CURIOUS action between two medical men relative to the sale of a practice was heard in the London courts, when Dr. Francis Whitaker sued Dr. Charles Harold Walker M'Cullagh, to recover £325, balance of the agreed price of a medical practice in the Hornsey road, which plaintiff sold to the defendant. There was a counterclaim for alleged slander. From the statement of counsel for the defence it appears that the plaintiff had sold his practice and joined a Religious Order in Ireland. The defendant had been attached to a North-West London hospital for ten years. In 1905, in reply to an advertisement, he saw Dr. Whitaker with regard to his practice, and ultimately bought it

Dr. Francis Whitaker, the plaintiff, said that he himself worked up the business in Hornsey. In May, 1905, he decided to join a religious order in Ireland, and determined to sell his practice, which brought in about £780 a year, excluding the appointment of St. Pelagius' Home. He told Dr. M'Cullagh that if he took the practice it would probably decline at first to £500 a year, and he agreed to sell it to the defendant for £650, a reduction of £100 on the price first asked. Witness said he did all he could to secure for defendant the various appointments he had held.

The jury found for the plaintiff on the claim and the counterclaim.

The Derbyshire Parliamentary Vacancy.

Dr. J. Court, undaunted by the three defeats he has sustained in the constituency, is to stand as Conservative candidate for North-East Derbyshire, and intends to make another bid for victory. He has lived and worked in that mining district for the greater part of his life, and has carefully studied the diseases peculiar to miners. On these and other grounds the miners have high appreciation of his work. Dr. Court is an honorary member of the Derbyshire Miners' Association, and consulting surgeon for that body in arbitration cases. He was born in Warwick in 1841, and his early studies were at the King Henry VIII. School in that town, and subsequently his medical course was continued at Guy's Hospital. Dr. Court's connection with Derbyshire dates back to 1864, when he commenced to practise at Staveley, at which place he has since resided. He is a licentiate of the Royal College of Physicians, and a member of the Royal College of Surgeons.

Sickness on Board Ship.—Failure to Report.

At a meeting of the Manchester Port Sanitary Authority recently, a long discussion took place in connection with a steamer at the Salford docks. A sailor who had left the vessel at Salford was found five days later to be ill, and nine days from leaving the vessel he was removed to the Ladywell Sanatorium suffering from typhoid fever. The inspector to the authority had gone over the vessel in port, and had received no information of sickness on board. The captain, written to subsequently, said the man left the ship well, and rode home on his bicycle. Dr. Dearden, medical officer to the authority, mentioned a worse case which had recently occurred, and said it was regrettable that captains were not bound to report sickness. In his monthly report Dr. Dearden stated that he was endeavouring to devise a scheme for obtaining notification of all cases of sickness of whatever nature, and added: "The slackness which exists among ships' officers on so serious a matter as proper investigation into the nature of sickness before anyone affected can leave the vessel is lamentable. In the interests of the public it is highly important that this state of affairs should be remedied." Several members expressed the opinion that in bad cases a notification should be sent to the port for which the vessel had left that the particular vessel had had on board a case of infectious disease. An arrangement for the interchange of information on these lines was suggested as a partial remedy.

A State Medical Service for Ireland.

THE Leinster Branch of the British Medical Association at its last meeting adopted the following resolution proposed by Dr. James Craig, and seconded by Sir J. W. Moore:—"That the Dublin Division of the Leinster Branch of the British Medical Association offers its congratulations to the members of the Viceregal Commission on the Irish Poor-law system on the ability and care displayed in the drafting of this report, the suggestions of which are made in a broad and statesmanlike manner, and that the Dublin Division heartily approves the formation of a properly remunerated State Medical Service of the entire Poor-law Medical Service, as it is certain to be a distinct advantage to the treatment of the sick poor in Ireland." The Central Council of the British Medical Association also adopted a somewhat similarly worded resolution.

Royal College of Physicians and Surgeons, England.

The following candidates passed the second professional examination in anatomy and physiology, held on the 3rd to the 8th January, by the Conjoint Board, viz.:—

Guy Oldham Chambers, John Joseph Clake, William Thomas Clarke, Henry Gray Woodhouse Dawson, Henzell Howard Dummere, Frederick Dunphy, Edwin Charles East, Alfred James Graves, Geoffrey Richard Heard, Gilbert Percy Humphrv, Roger Percival Jones, Fritz Kahlenberg, James Arthur Richard Lee, Charles Eric Lowe, Alexander Ernest McKenzie, John Charsley Mackwood, John Mitchell Mehaffey, Douglas Ashley Mitchell, Leonard William Mortimer, Humphrey Neame, Richard Alfred Parsons, Richard Biddulph Phillipps, Edward Holmes Rainey, Harold Thwaite, Francis Christopher Tibbs, George Ernest Vilvandré, John Glegg Watson, Charles FitzGerald Willes, Sydney Williams, Charles Stewart Wink, Duncan Wood, and Charles Reynolds Woodruff.

Conjoint Examinations in Ireland.

THE following candidates have passed the First Professional Examination:—J. H. Barry, J. Boyce, H. J. Burke, P. J. Burke, F. Cassidy, Miss M. M. S. Coghlan, J. J. Foran, R. A. W. Ford, P. Grace, H. A. Harbison, C. Lenahan, H. C. Smyth,

The following have passed the Second Professional Examination:—E. A. Gregg (with honours), R. Charles, T. M. Duncan, J. W. Flood, A. E. Moore, W. Mulcahy, T. McDonald, W. P. H. Parker, C. O'B. Ryan, D. K. Seaver, O. H. Woods.

The following have passed the Third Professional Examination:—P. H. Black, R. J. Bonis, F. Byrne, A. Curry, H. E. Davis, M. B. Dooley, P. A. Doyle, J. J. Dwyer, J. A. J. Flannery, G. A. Finegan, P. Harrington, M. J. Hawkshaw, P. Maguire, A. E. S. Martin, P. McCarthy, D. McCormack, P. J. Timoney, E. C. Wallace, J. F. Walsh, A. Warnock.

Society of Apothecaries, London.

THE following candidates, having passed the necessary examinations, have received the L.S.A. Diploma of the Society, entitling them to practise medicine, surgery, and midwifery: O. P. N. Pearn and D. E. C. Pottinger.

Weekly Summary of Medical Literature, English and Foreign.

Specially compiled for The Medical Press and Circular.

Chylous Dropsy.—Sonmer (*Deut. Arch. Klin. Med. Leipsig*, 1906) relates a case of profuse milky effusion requiring repeated tapping in a woman of 51. A carcinoma was found in the ovary, and, in the apparently intact walls of the thoracic duct, nests of cancer cells were found, explaining the permeability. D.

Coagulating Power of Blood Serum in Epileptics.—Besta's researches (*Riforma Med. Naples*) confirm those of Ceni in regard to the specific modification of the composition of the blood in epileptics. The modification seems to be constant in the individual, not varying with the seizures, consequently the latter cannot be regarded as the explosive throwing oft of morbid products. The proportion of fibrin ferment in the blood is much below normal, according to his experience, and as the fibrin ferment is an organic compound of lime, it follows, he thinks, that the epileptic may be suffering from a lack of lime. D.

Differential Diagnosis of the Diseases Hitherto Grouped Together as Rheumatoid Arthritis.—Nathan (*Am. Journal of the Medical Sciences*, Dec., 1906) divides diseases hitherto grouped under the name of rheumatoid arthritis into two classes—(1) those which begin acutely, the inflammatory or infectious forms; and (2) those of insidious onset, the trophic forms. Of the first class he describes four types of cases—(1) mild cases, which, however, may lead to some permanent disability; (2) similar cases with more fever and more severe joint symptoms, some with glandular enlargement described as Stell's disease; (3) cases simulating rheumatism, with high fever and often endocardial and renal complications, leaving permanent joint disability; and (4) cases associated with other infectious diseases, such as typhoid and gonorrhœa. D.

The Rôle of Nuclein in the Animal Economy.—McCaskey (*Journal of the American Assoc.*, Dec., 1906) has determined the amounts of uric acid and of phosphoric acid in the urine of a large number of patients, in an attempt to measure roughly the amount of nucleins represented by these substances, which are their cleavage products. The nucleins of the body are widely distributed, but occur especially in the nuclei of the cells. They are of interest for their own properties, and as antecedents of the purin bodies, including uric acid. The nucleins have some germicidal power; they may be active in bacteriolysis and in production of phagocytosis; the toxins of diphtheria and tetanus are precipitated by nucleinic acid. Uric acid is not toxic, causing symptoms only as a mechanical irritant when precipitated. The results of the analyses are tabulated. The excretion of uric acid (and presumably of other purin bodies) was most strikingly increased in Bright's disease. D.

Cirrhosis of the Pancreas.—Schmieden (*Mun. Med. Woch.*, 1906) reports a case of cirrhosis of the pancreas causing puzzling symptoms and leading to great debility. An exploratory laparotomy cleared up the diagnosis and allowed appropriate treatment, which restored the patient to health. The patient was a woman, æt. 24, with healthy children. A painful knobby tumour corresponding to the head of the pancreas was accompanied by typical pancreas colic and pronounced delay in the glutoid test. Three weeks after the birth of the last child the first attack of colic came on; the pain was more in the median line than in case of gallstone colic, and radiated in the back to the shoulder, especially on the right side, with paroxysmal sweating. The patient could not bear to have her clothes buttoned, and frequently was obliged to stay in bed for a day or so, and was unable to stoop. The pains had no connection with the taking of food, but vomiting occurred two or three times a day, free from blood. The response to Sahli's glutoid capsules did not appear for 21 hours, showing abnormal delay. There was no fever; neither was there albumen or sugar in the urine. The pancreas was found knobby and enlarged, and embedded in old leathery adhesions. A wedge-shaped piece was cut out of the head of the pancreas and abdomen closed. No evidence of fat necrosis was disclosed. The patient was treated with a pancreatic preparation and potassium iodide, and recovered completely. The microscope revealed typical severe cirrhosis of the pancreas, free from any tendency to tumour formation. Another woman presented absolutely the same clinical picture, only the cachexia was less marked, but the microscope revealed alveolar carcinoma. D.

The Paravertebral Triangle of Dulness in Pleural Effusion.—Thayer and Fabyan (*Amer. Journ. Med. Scien.*, January, 1907) discuss the value of this sign in the diagnosis of pleural effusion. The sign was originally described by Grocco in 1902, and has been since accepted by the majority of writers on the subject as one of considerable value. The writers of the present paper have made a special examination of it in thirty-two cases of pleural effusion, and find the sign practically constant in cases where there is free fluid in the pleural cavity. This triangle is an area of relative dulness, the vertical side of which is represented by the line of the spines of the vertebræ, the apex reaching a point somewhat above the level of flatness of the effusion; the base is formed by the lower limit of pulmonary resonance on the healthy side for a distance of from 2 to 7 cm. from the spine; the hypothenuse by a line connecting these points. The last line shows sometimes a slight outward convexity, and the dulness is more marked as one approaches the spine. The dulness disappears, or becomes markedly less, if the patient lies on the affected side, but returns again when the erect posture is assumed, or when the patient lies on the other side. The triangle is usually larger on the left side—that is, in the case of right-sided effusions—than on the right. The authors are inclined to accept the explanation given of the phenomenon by Baduel and Siciliano, namely, "that the fluid lying against and passing anteriorly over the bodies of the vertebræ acts as a mute in suppressing the sonorous vibrations of the spine." Very rarely has anything in the nature of a paravertebral triangle of dulness been demonstrated in cases of consolidation of the lung, and in the rare instances in which it was found little or no change could be demonstrated in it on change in position of the patient. K.

Treatment of Scabies with Balsam of Peru.—Robinson (*R.A.M.C. Journal*, January, 1907) reports the results of the treatment of thirty-seven patients as recommended by the "Third Report of the Advisory Board for Army Medical Services." Colonel Robinson has made some alterations in the method of treatment suggested by the report. The patient on admission to hospital is given a hot bath and thoroughly scrubbed with soap and water. He is then quickly dried, and at once rubbed over with the following preparation:—Balsam of Peru, three parts, and glycerine, one part. The balsam is applied to the whole body "with an old nail-brush, soft from long usage, and well rubbed into the flexures and crevices of the skin. He dresses in clean clothes, and remains in hospital till his bedding and clothing are disinfected (usually three days); he is then discharged, to attend once a week for a month at the hospital for observation." "The patient should not be allowed to bathe till four weeks have elapsed, *i.e.*, until he is free from all danger of relapse. Should there be any subsequent return of the itching, which is unusual, the man is detained for a day, bathed, and has a further application of the balsam to the itchy parts." The three most important points in the treatment are thorough scrubbing in the bath, thorough application of the preparation immediately after the patient is dried, and complete abstinence from baths for four weeks after the first application. It was through neglect of the last of these rules that many of the earlier cases treated proved unsatisfactory, and since it has been rigidly enforced the results have been uniformly good. In no case was any subsequent dermatitis met with. K.

Adams-Stokes Disease.—Ashton, Norris, and Lavenson (*Amer. Journ. Med. Scien.*, January, 1907) report the case of a patient who died in hospital from this disease, and in whose heart on *post-mortem* examination a gumma was found in the interventricular septum. The patient was a man, æt. 30 years, who gave no history, and showed no signs of syphilis. His cardiac symptoms dated from four days before admission to hospital, when he became unconscious in a tramcar, and during the next few days he had similar attacks. On admission to hospital his heart was found to be enlarged, his apex beat diffuse, first sound feeble and accompanied by a systolic murmur. The pulse rate was 48 per minute. While in hospital he had numerous attacks of syncope, during which his pulse rate was generally about eighteen per minute, increasing at frequent intervals to thirty. During one of these attacks, which occurred about three weeks after the onset of the disease, he died. On *post-mortem* examination some thickening of the mitral valve was found, and on histological investigation a gumma was found in the interventricular septum, which in one part completely interrupted the auriculoventricular bundle of His. K.

Aristochin.—Giordani (*Gaz. Internat. di Med.*, Bd. viii., April, 1906) has made use of Aristochin in an epidemic of whooping-cough, and also in malaria and other febrile diseases, with the object of determining its value as an anti-pyretic. Altogether he employed it in about 60 cases. He finds that, on account of its absence of taste, it is well and easily taken, and that it possesses the specific action of quinine on the plasmodium malariæ. It also acts well as an anti-pyretic and anti-neuralgic, while in pertussis the results were very encouraging, and in many cases a favourable influence in the course of the disease was plainly marked. The drug, which is a carbonic acid ester of quinine, was given in powder, or else suspended in milk, the dose being from .2 to .1 gramme in the 24 hours, according to the age of the patient and the severity of the case. M.

Phillippovich's Phenomenon in Typhoid Fever.—The symptom which has been described by Phillipovich as pathognomonic of typhoid fever consists of a peculiar yellow colouring of the palms of the hands and soles of the feet, such as would be produced by rubbing them with potassium nitrate and picric acid. The symptom has been observed also by French writers as being frequently present in typhoid, and some regard it as being produced by some alteration of tissue metabolism brought about by a specific toxin. Other authors, however, deny its importance as a diagnostic sign, and maintain that it may be observed in many other acute infections. They regard it as being merely the result of an excessive destruction of blood-pigment. Minuotti (*Gazz. degli ospedali*, 1906, No. 36) has lately observed the phenomenon in a typhoid patient in whom it appeared, along with severe pains in the hands and feet. Both pain and discoloration disappeared at the same time, from which fact the suggestion is made that possibly both were the result of a toxin acting both on the ordinary tissues and on the sensory nerves. M.

Myositis in Typhoid Fever.—Michalke (*Med. Klinik*, 1906, No. 34) observed during the convalescence of a typhoid fever case a rise of temperature with rigors on three distinct occasions. The first time there was great swelling and pain in the left leg; the second time there was pain and cramp in the right thigh, and on the third occasion the right leg was similarly affected. On each occasion the neighbouring chains of lymph glands became swollen and tender, and the leucocytes, which are normally lessened in typhoid fever, became increased in number. All this appeared to the writer to point to inflammatory processes in the muscles, and of a non-purulent nature, inasmuch as recovery took place in a few days. Such a non-purulent myositis must be rare, as a sequel to enteric fever, since no records of such can be found in the literature. M.

Heart Massage in Cases of Apparent Sudden Death.—Dr. T. A. Green (*Lancet*, Dec. 22nd, 1906) contributes an interesting paper on this subject, and gives an analysis of 40 cases in which heart massage was attempted, as well as describing in detail two cases of his own. The method had principally been employed for cardiac syncope under anæsthetics, especially in chloroform cases, but has also been occasionally tried in hanging cases, syncope in diphtheria, death from electric shock, and in brain injuries. In his own first case a trivial operation was being performed on a child aged 9, chloroform being administered. Syncope suddenly took place, and as other means failed to restore the heart action, the abdomen was opened 25 minutes after the accident, and direct massage of the heart was carried out through the diaphragm. Soon both cardiac and respiratory action became re-established, and the patient was brought back to bed in an unconscious condition, but with strongly-acting heart. Toxic spasms set in a little later, and returned in spite of treatment, the patient finally dying 20 hours after the restoration of heart-beat. Dr. Green's second case was one of sudden post-diphtheric syncope. Heart action was restored by the massage, but the respiratory rhythm did not become re-established, and so the effort to revive the patient failed. Out of the 40 cases analysed, a partial success was gained in eight, the longest time of survival being 24 hours, and the longest period of cessation of heart-beat prior to massage being 45 minutes. The writer, though not very enthusiastic, thinks that there is a future for this treatment in desperate cases, and gives the outline of a definite method of procedure which he intends in future to adopt. M.

Epigastric Pain in Emphysema and in Heart Disease.—De Brun writes (*Rev. de Méd.*, 1905, p. 981), on the occurrence of epigastric pain in pulmonary emphysema. He points out that it is very frequently present in a more or less severe form, and out of fifty cases it was so bad in five as to simulate gastric ulcer, biliary colic, and other severe abdominal conditions. It is usually situated in the middle line at the tip of the ensiform cartilage, sometimes a little higher, and more frequently at a lower level and to the left. As a rule, it is definitely circumscribed, is nearly always continuous, and tends to be worse at night. It is increased by movement, and pressure may cause it to become almost unbearable. The pain may be present quite early, and indeed is not uncommonly the earliest subjective sign of emphysema. It in no way depends on the condition of the stomach or its blood supply, and can be distinguished from colic due to arteriosclerosis by the fact that this last-named pain is not made worse by pressure. A similar pain is present when the right ventricle is over-distended, and is thus often seen in mitral disease with failing compensation. M.

NOTICES TO CORRESPONDENTS, &c.

☞ **CORRESPONDENTS** requiring a reply in this column are particularly requested to make use of a *Distinctive Signature or Initial*, and to avoid the practice of signing themselves "Reader," "Subscriber." "Old Subscriber," &c. Much confusion will be spared by attention to this rule.

L. N.—Poisoning symptoms have been noted from the use of sesame oil as an enema, but further investigation seems to point to the oil from French sources being at fault. The German oil is said to be harmless.

PREVENT.—In America the matter has attracted more notice than here, and the Vermont State Board of Health last year issued to each medical practitioner in the State a packet of leaflets containing directions for the avoidance of the spread of syphilitic infection. They asked that these might be given by the doctors to all their syphilitic patients.

WHY DOCTORS STARVE.

A TIVERTON Guardian on one occasion expressed a public hope that the doctors "will write more plainly this year, whereupon the *Daily News* published the following verses:—

Dear Doctor,—If it's not too late
To frame a New Year's vow,
Accept this copy book and slate,
And bring your pot-hooks up to date
Deliberately now.

Poor Tom is raving with the pain
Your last prescription gave;
The lotion mixed for Teddy's blain
Has brought his earache on again;
The pills have crippled Dave.

How small your yearly total sounds!
I send remittance due.
Please say when next upon your rounds
If it is two or twenty pounds—
I've made it out for two.—A. W.

MERROW.—"Barlow's Disease" is the same as "infantile scorbutus." It is disputed as to whether there is any necessary connection between Barlow's disease and rickets, the change it is said being in the lymphoid marrow, which is atrophied.

DR. P. N.—The operation has been described several times in the last few years in our "Operating Theatres," and you will glean most of the information you require if you run your eye over the cases described therein. The question as to whether a patient is a fit subject for removal of the prostate involves many considerations, for apart from his general health it is well to be assured as to the character of the prostatic enlargement. If on bimanual examination a moderately large growth projecting towards the interior of the bladder and freely movable is felt, the operation is generally indicated.

"MORE LIGHT."—Red light has been tried in scarlet fever as well as in small-pox. It is said that by excluding all light except red from the patient's room night and day the fever and rash are averted, but complications are not affected. The results as reported, however, do not carry much conviction to our mind.

SESTOS.—We do not know the brand of whisky named, nor can we trace any reference to it. The distillers will probably reply if you write to them and say whether it is a pot-still whisky or a blend.

Meetings of the Societies, Lectures, &c.

WEDNESDAY, JANUARY 30th.

BRITISH BALNEOLOGICAL AND CLIMATOLOGICAL SOCIETY (20 Hanover Square, W.).—5.30 p.m.: Discussion on the Influence of Climate upon Gout, Rheumatism, and Rheumatoid Arthritis (introduced by Dr. C. W. Buckley (Buxton). Dr. J. Groves (Isle of Wight), Dr. H. Cumming (Torquay), Dr. P. Lewis (Folkestone) and others hope to take part in the discussion.

MEDICAL GRADUATES' COLLEGE AND POLYCLINIC (22 Chenies Street, W.C.).—4 p.m.: Mr. P. L. Daniel: Clinique. (Surgical). 5.15 p.m.: Lecture:—Dr. H. L. Jones: Cervical Ribs and Muscular Atrophy of the Hands (with lantern slides).

NORTH EAST LONDON POST-GRADUATE COLLEGE (Tottenham Hospital, N.).—2.30 p.m.: Cliniques:—Dermatological (Dr. Meachen), Ophthalmological (Mr. Brooks), Medical Out-patient (Dr. Whipham). Lecture:—Mr. R. P. Brooks: Ocular Headaches.

THURSDAY, JANUARY 31st.

OPHTHALMOLOGICAL SOCIETY OF THE UNITED KINGDOM (11 Chandos Street, Cavendish Square, W.).—8 p.m.: Card Specimens. 8.30 p.m.: Papers:—Mr. S. Snell: (1) A Case of Tubercle of the Eyeball in which the Opsonic Index was regularly taken; (2) A Family Tree of Nyctalopia. Mr. A. Lawson: Two Cases of Streptococcic Infection of the Conjunctiva. Mr. G. B. James: Some Notes on Stereoscopic Vision.

MEDICAL GRADUATES' COLLEGE AND POLYCLINIC (22 Chenies Street, W.C.).—4 p.m.: Mr. Hutchinson: Clinique. (Surgical). 5.15 p.m.: Lecture:—Mr. L. Mummery: Rectal Hæmorrhage, its Causation and Treatment.

NORTH-EAST LONDON POST-GRADUATE COLLEGE (Tottenham Hospital, N.).—2.30 p.m.: Gynæcological Operations (Dr. Giles), Cliniques:—Medical (Dr. Whiting), Surgical Out-patient (Mr. Carson). 3 p.m.: Clinique:—Medical In-patient (Dr. Chappel). 4.30 p.m.: Lecture:—Dr. Macdonald: The Pathology of the Pneumonias.

ST. JOHN'S HOSPITAL FOR DISEASES OF THE SKIN (Leicester Square, W.C.).—6 p.m.: Chesterfield Lecture:—Dr. M. Dockrell: Treatment (Constitutional and Local in all its Forms).

FRIDAY, FEBUARY 1st.

SOCIETY OF ANÆSTHETISTS (20 Hanover Square, W.).—8.30 p.m.: Paper: Dr. L. Guthrie: Poisonous After-effects of Chloroform and of Ether.

MEDICAL GRADUATES' COLLEGE AND POLYCLINIC (22 Chenies Street, W.C.).—4 p.m.: Dr. D. Grant: Clinique. (Ear).

NORTH-EAST LONDON POST-GRADUATE COLLEGE (Tottenham Hospital, N.).—9.30 a.m.: Clinique. Surgical Out-patient (Mr. H. Evans). 2.30 p.m. Surgical Operations (Mr. Edmunds). Clinique. Medical Out-patient (Dr. Auld), Ophthalmological (Mr. Brooks), 3 p.m. Clinique. Medical In-patient (Dr. Leslie).

Vacancies.

West Riding Asylum, Menston, near Leeds.—Second Assistant Medical Officer. Salary £200 per annum, with board and apartments. Applications to the Medical Superintendent.

West Riding Asylum, Menston, near Leeds.—Fourth Assistant Medical Officer. Salary £150 per annum, with board and apartments. Applications to the Medical Superintendent.

East London Hospital for Children and Dispensary for Women, Shadwell, E.—Resident Medical Officer. Salary £100 per annum, with board, residence, and laundry. Applications to W. M. Wilcox, Secretary.

Stroud General Hospital.—House Surgeon. Salary £100 per annum, with board, lodging, and washing. Applications to the Hon. Secretary.

Newcastle-upon-Tyne and Northumberland Sanatorium for Consumption, Barrasford-on-Tyne.—Resident Medical Officer. Salary £180 per annum, with board and laundry. Applications to Secretary, 13 Grey Street, Newcastle-upon-Tyne.

North Lonsdale Hospital, Barrow-in-Furness.—House Surgeon. Salary £100 per annum, with board and lodgings. Applications to Secretary. North Lonsdale Hospital, Barrow-in-Furness.

King Edward VII. Sanatorium, Midhurst, Sussex.—Junior Assistant Medical Officer. Salary £100 per annum, with board, lodging, and attendance. Applications to the Hon. Secretary, 19 Devonshire Street, Portland Place, London, W.

The Royal Hospital for Diseases of the Chest, City Road, E.C.—Resident Medical Officer. Salary £120 per annum, with furnished apartments, board, and washing, Applications to the Secretary.

Newport Borough Asylum, Caerleon, Mon.—Assistant Medical Officer. Salary £170 per annum, with board, apartments, and attendance. Applications to the Medical Superintendent.

Royal Cornwall Infirmary, Truro.—House Surgeon. Salary £100 per annum, with board and apartments. Applications to J. C. R. Crewes, 4 Parkvedras Terrace, Truro.

Monaghan Asylum.—Resident Medical Superintendent. Salary £500 per annum, with house, fuel, &c. Applications to R. L. Donaldson, Acting R.M.S.

Appointments.

HOSFORD, J. STROUD, F.R.C.S.Edin., Honorary Assistant Surgeon to the Royal Eye Hospital, Southwark.

MARKS, URBAN, M.R.C.S., L.R.C.P.Lond., House Physician at the Worcester Infirmary.

POLLARD, G. S., M.R.C.S., L.R.C.P.Lond., Certifying Surgeon under the Factory and Workshop Act for the Midsomer Norton District of the county of Somerset.

ROSS, S. J., M.D.Vict., Certifying Surgeon under the Factory and Workshop Act for the Bedford District of the county of Bedford.

WATKIN, ARTHUR CHRISTOPHER, L.R.C.P.Lond., M.R.C.S., House Surgeon at the Aberystwyth Infirmary.

YOUNG, J. STIRLING, M.B., Ch.B.Vict., Fourth House Surgeon at St. Mary's Hospitals, Manchester.

Births.

COOKE.—On Jan. 26th, at 69 Bridge Street, Cambridge, the wife of Arthur Cooke, F.R.C.S., of a son.

ELLIS.—On Jan. 23rd, at 208 London Road, Leicester, the wife of L. Erasmus Ellis, M.D., of a son.

GILBERTSON.—On Jan. 25th, at Southbourne Lodge, Southampton, Hants, the wife of William Gibertson, M.A., M.D., of a son.

ROGERS.—On Jan. 24th, at 28 Sutherland Avenue, London, the wife of David de Sola Cohen Rogers, L.D.S., R.C.S.Eng., of Buenos Ayres, of a son.

Marriages.

AVELING—SHIMWELL.—On Jan. 23rd, at St. Wilfrid's Church, Northenden, Leslie Baldwin Aveling, B.A., M.B., B.C., of Royton, son of the Rev. F. W. Aveling, M.A., B.Sc., of Blackheath, London, to Dorothy, second daughter of W. J. Shimwell, of Gatley, Cheshire.

CARBERY—HUTTON.—On Jan. 23rd, at Bath, Staff-Surgeon E. O. B. Carbery, R.N., son of the late Edward Spencer Carbery, to Amy Muriel, elder daugher of Thomas Hutton.

JEANS—BARRY.—On Jan. 24th, at St. Luke's Church, Liverpool, Frank A. Gallon Jeans, M.A., M.B.Cantab., son of A. G. Jeans, of Birkenhead, to Eveline, second daughter of the late Garrett J. Barry, of Liverpool, and of Mrs. Barry, Rockferry.

Deaths.

OLDHAM.—On Jan. 24th, at 38 Brunswick Square, Brighton, Charles James Oldham, F.R.C.S., eldest son of the late James Oldham, of Brighton, aged 62.

SPENCE.—On Jan. 25th, John Utley Spence, 50 Rosendale Road, West Dulwich, eldest son of the late John Spence, M.R.C.S., L.R.C.P., Bedale, Yorks.

PURLEY, SURREY.

A road has now been made through that little piece of the old forest lands of Surrey known as THE FURZES, which offers the unusual opportunity of erecting a new house in an old garden; the land is about 400ft. above sea level, with a gentle South slope: and only ten minutes from the station; detached houses of approved design to be erected on not less than one acre each: the road has kerb, channel, sewer, S.W. drain, gas and water mains, and is considered to be not only the prettiest but the best made in the neighbourhood.—Plan and particulars may be obtained of Mr. Winborn. Furze Lane, Purley.

TO YOUNG MEDICAL MEN.—Splendid opening for Dispensary Practice. Populous suburb S.E. Double-fronted detached house, corner of two roads, everyconvenience, for sale £75 cash, balance could remain at 5 per cent. 71 years lease, low ground rent. (Sold by order of administrator.)—Apply Hatch and Hatch, 62 Rushey Green, Catford.

THE MEDICAL PRESS AND CIRCULAR.

"SALUS POPULI SUPREMA LEX."

VOL. CXXXIV. WEDNESDAY, FEBRUARY 6, 1907. No. 6

NOTES AND COMMENTS.

Non-Professional Attendance.

JUDGE O'CONNOR, of the Sunderland County Court, has ideas about professional attendance on the sick which suggest the conundrum : When is medical attendance not medical attendance ? The answer would seem to be : When the doctor expects a fee. The other day, in Sunderland, Dr. Cunningham was summoned by the foreman of Messrs. Greenwell and Co., ship repairers, to attend to a workman who had a fit. The summons was duly observed, and Dr. Cunningham did all there was to do for the patient, eventually putting him on a stretcher and conveying him from the ship's hold to a cab. When the question of a fee was raised in due course, the firm, with that despicable meanness which characterises the relations of many large trading concerns towards medical men, refused to recognise the obligation. Dr. Cunningham stood by his rights so far as to sue Messrs. Greenwell and Co. in the County Court for a guinea for the services he had rendered. The judge, however, would not hear of the claim. What Dr. Cunningham had done, he said, was the sort of thing that nurses, policemen, and ordinary pedestrians did ; it was not professional attendance. He would give judgment for the defendants with costs. Are we to conclude, then, that the law of the land does not recognise a doctor's services in an emergency as "professional," because doctors have taught lay people how to render first aid ? Would the learned judge decline to receive his salary because medical men, journalists, and other non-legal folk also consider themselves capable of forming a rational judgment ? Whether he would or not, we may be allowed to state that in our judgment his decision is a preposterous one, and that the country pay handsome salaries to County Court judges in order to get good judicial work from them, and not pettifogging quibbles of the Stareleigh order.

One Stroke, One Orange.

THE stand which the MEDICAL PRESS AND CIRCULAR always takes against stupid punishments and other relics of barbarism in the treatment of prisoners, has brought us some notes from a correspondent about the flogging of boys by magistrates' orders. It may well be that, in time to come, when humanitarianism and discretion have permeated our modes of punishment, flogging may be altogether abolished, but it would require more boldness than we possess to say that whipping young boys can be entirely done away with. Indeed, as a means of correction we greatly prefer a few strokes of the birch, especially applied by the offender's father, to the stupidity of imprisonment or the ineffectiveness of a fine. In one of the cases brought to our notice a lad, aged ten, was charged before the magistrate with stealing oranges, and he was ordered a stroke of the birch for each orange stolen. That seems a fair compromise, especially as the prosecutor allowed the oranges to be retained to efface the smarting of the rod. The point that we would make ourselves is the positive wickedness of bringing a child of such tender years into contact with the police-court and its associations for an offence so puerile. Indeed, if the prosecutor could have been ordered three strokes for each given to the boy, justice would have vindicated its character for evenhandedness more completely.

Bipolar Version.

The solicitude of the State for the protection of the midwife is almost as marked a feature of its policy as its airy neglect of the public interest in every other medical and quasi-medical respect. At Mansfield, the other day, a woman who had practised as a midwife for twenty years, and was known to the authorities as a clean and respectable person, was prosecuted by the County Council for calling herself a midwife when she was not on the roll, and in the end a conviction, with a fine, was obtained. The woman seems to have been a very favourable specimen of her class ; she had attended some four or five thousand cases of midwifery in her time, had testimonials and certificates from medical men in the town, and had applied not only for admission to the register, but also for leave to attend midwifery lectures in the town. She was refused registration twice, although she was entitled to it under the Act, because, owing to a misunderstanding on her part, she applied too late, and she was refused admission to the qualifying county lectures for the paradoxical reason that she was not qualified. To ring down a successful curtain on this delightfully Gilbertian situation, she was prosecuted by the county authorities. So the unfortunate woman was had every way. The principle of "Heads I win, tails you lose" should now be clear to her unsophisticated brain, and doubtless if she is sufficiently educated to read a text-book on midwifery, bipolar version will acquire new meanings for her.

Aerated Milk. The problem of keeping milk for infant use at once fresh and sterile has racked many brains of late, but a Mr. Randolph Hemming has, it is claimed, solved it at last. By a process of his own devising he can so introduce carbonic acid gas into milk that bacteria are destroyed, and the milk is preserved in all its pristine and nutritious vigour. Milk, like champagne and soda-water, can be ordered in by the dozen, and the joys of aërated beverages are no longer to be reserved till puberty, when lemonade is acceptable, or manhood, when nothing with a sparkle comes amiss, is reached. From the moment of entering the world, the young human will be accustomed to the joys that accompany the stimulation of the gastric mucosa with bubbles of gas, and the popping of the cork will cheer him in the nursery even more frequently than it does his sire in the dining-room. To every advance in science there are corresponding drawbacks, and we fear there are selfish persons who will be inclined to resent even this boon if their sleep is to be disturbed on warm nights by the violence of starting corks and the domestic catastrophes that accompany them. The present troubles from "wind in the stomach" are likely, we should judge, to be nothing to what this vista opens out before us.

"Slink" Meat. Our contemporary, the *Manchester Evening Chronicle*, deserves much congratulation for the success that has attended its revelations on the "slink" meat trade. One of the results of its *expose* is that two Gorton butchers have been detected in their operations and sent to gaol. The method employed by these scoundrels seems to have been to convey into Gorton by night meat from diseased animals killed in the country. Saturday was the chief day for its sale, when in the working-class districts the pestilential stuff was sold by mock auction, at ridiculously low prices. The police and sanitary authorities, becoming aware of the dodge, laid a trap, as the result of which they seized a quantity of meat described as showing signs of tuberculosis and giving off a "fever smell" when cut into. It is very encouraging that although the meat had not actually been sold, the magistrate should have visited the offence with such a severe penalty—imprisonment without option of a fine—because in such cases prevention is of the essence of protection for the public. Yet in a case at Battersea last week a butcher who was summoned for having in his slaughter-house an ox suffering from extensive tuberculosis, signs of which, according to medical and veterinary evidence, must have been present during life, was let off by the magistrate because there was no evidence that the meat was intended for sale. "The Council's officers were too premature," he said. If stopping diseased meat from being sold to the public is considered acting prematurely, we can only hope that all councils will encourage the breed of similar hasty officials.

The Hair and the Dog. In these cosmetic days, when the causes of baldness are debated annually throughout the dermatological societies of Europe, it is something of a relief to be able to fix on at least one very concrete cause—to wit, dog-bite. It is not, it seems, necessary that the bite should be applied *in situ*—in fact, any convenient part, such as the calf, may be chosen for the purpose, and yet the hair will fall out from the scalp in due time. In the Marylebone County Court last week a young lady who had been bitten by a dog sought and obtained damages against its owner, one of the special features which entitled her to remuneration being that as a consequence of her fright and shock, her hair fell out in patches. Being still young, the lady may look forward to a replenishment of her locks, said the medical witness, though had she been over forty the prognosis would have been gloomy. Without committing ourselves to these views *in toto*, we can imagine that this specific instance will come as a shock to the advocates of the bacterial origin of alopecia areata, but we can also see a fine opportunity for the vendors of hair-restorers, for in this case, where the hair is bound to grow again, what a safe cure would be wrought by any nostrum applied! Probably the lady in question will be inundated with advertisements; the most sagacious firm would be that which would supply "free samples." Its testimonial would be assured.

LEADING ARTICLES.

"PROFESSIONAL MISCONDUCT" IN THE LAW COURTS.

The chaotic state of the laws that regulate and govern the medical world has long been an object of ridicule, satire, and ineffectual remonstrance. Unwritten rules of Draconian severity are administered with iron hand either by the sheer force of professional opinion or by the action of medical associations and corporate bodies. The difficulty of enforcing rules that have never been properly defined by bodies whose *locus standi* often rests upon no firmer ground naturally ends now and then in more or less of a deadlock. Take, for instance, the constantly recurring question of professional advertising. It would be impossible to draw up any satisfactory statement of what does and does not constitute "advertising" as it is commonly regarded by the General Medical Council. In extreme cases there would be little or no difficulty in deciding one way or the other, but in a vast number of instances there would be a great deal to be said on both sides. An illustration of these remarks may occur to readers in the case of a North Country medical man who some years ago was taken to book by the British Medical Association for putting his name on the gates of an institution devoted to some quite legitimate method of treatment. In subsequent lawsuits the fact transpired that a prominent London consultant, a Fellow of the Royal College of Physicians, who came to testify to the unprofessional character of the plate, had his own name and address distributed broadcast to the public at the foot of calendars issued by a large insurance company. The whole world of medicine was roused to Gargantuan laughter at this unexpected turning of the tables, and the case against the humbler practitioner not unnaturally collapsed. The jurisdiction of the General Medical Council, however, armed with its penal clauses, has hitherto been regarded with due respect as an all-powerful tribunal, whose decisions were final in the matter of ethical offences. But this belief has been utterly destroyed by a recent decision of Mr. Justice Warrington, delivered in the case of Clifford *v.* Timms on January 29. Both parties to the suit were dentists, and as such came under the disciplinary control of the General Medical Council. Mr. Clifford had a private practice in Grosvenor Street, and took Mr. Timms into partnership. Later, on account of an interview published in the *Review of Reviews* with the American Dental Institute, of which Clifford was a director, he was adjudged by the General Medical Council to have been "guilty of infamous and disgraceful conduct in a professional respect," and his name was removed from the *Dentist's Register*. The defendant, Timms, acting upon a clause in the partnership agreement, attempted to sever his connection with plaintiff, who thereupon brought an action to insist upon the continuance of the partnership. The point upon which the plaintiff relied was the denial of unprofessional conduct. This argument practically brought the decision of the General Medical Council before the Law Courts for review. Upon that clearly defined issue the case hinged, and assuming that right of review, Mr. Justice Warrington delivered a judgment that is momentous, not only to members of the dental profession, but also to every medical practitioner in the British Empire. The General Medical Council, after due enquiry, find Mr. Clifford guilty of professional misconduct and remove his name from the *Register*. His partner attempts to dissolve partnership with the disqualified man. The latter appeals to the Law Courts, with the result that a judge declares him not to have been guilty of unprofessional conduct, therefore the partnership cannot be dissolved on that score. This overriding of the Council's action sets up a situation that is simply untenable. Mr. Timms is now tied for life to an unqualified practitioner. The only logical course open to the General Medical Council is to prosecute Timms for "covering" an unqualified dentist. If the ruling in this case be upheld every man in medical partnership throughout the kingdom may at any moment find himself in a precisely similar predicament. Moreover, every decree of the General Medical Council disregistering a qualified practitioner will be open to an appeal in the law courts. What is to happen now in the case of Clifford. A high court of law has declared him not guilty of unprofessional conduct. How, then, can the Council refuse to reinstate him in the possession of his right to legitimate practice? If Mr. Justice Warrington be right, then we must bid farewell to the future effectual control of the Council over wrongdoers. But the matter is not likely to end here. The principle involved is one of such supreme importance to the authority of the Council that it is certain to be raised in some form or other for further trial. The high-handed attitude of Mr. Justice Warrington may be gathered from his demand, on subpœna, of confidential documents in the possession of the General Medical Council. By some more or less subtle legal hair-splitting, one of the documents was produced in court, but the point as to the legality of the demand was left undecided. In conclusion we submit that there should be no loss of time in testing the assumption of an English judge to override the powers conferred on the General Medical Council by the Medical Acts. In any case the profession is sadly in want of an amending Act, whereby the whole guidance, control, and defence of the profession should be placed on a basis more in accordance with modern views as to the proper constitution, powers, and administrative methods of a great judicial and controlling authority like the General Medical Council.

THE REPORT OF THE ROYAL TUBERCULOSIS COMMISSION.

The second interim report of the Royal Commission appointed some six months ago to inquire into the subject of tuberculosis has just been published. Its importance is obviously great, although it is hardly possible to estimate at the present moment its precise significance in the prevention of the disease. There can be little doubt, however, that this report of the British Royal Commission will form one of the great landmarks in the history of the scientific study of tuberculosis. The ball was set first rolling effectually by Koch's discovery of the specific micro-organism in 1882. Great strides were subsequently made in the treatment of the disease by bettering the environment of infected individuals. But the broad general questions of prevention have never been hitherto seriously attacked. The crucial points of the identity of tuberculosis in man and in the lower animals, for instance, was in dispute, with the consequent and correlated questions of the infectivity of the flesh and milk of lower animals used as the food of man. The terms of the reference, it may be well to remind readers, were to ascertain whether the disease in the lower animals was identical with that in man, whether infection might be reciprocal, and, if transmissible, under what conditions it was conveyed. These points were raised in consequence of the sensational announcement by Koch at the International Medical Congress, held in London in 1900, to the effect that human tuberculosis in man and in the lower mammalia were distinct maladies not communicable from one to the other. If accepted, that theory would have swept away the whole of the proposals for a vast machinery of prevention by the extermination of tuberculosis in all animals utilised for human food, whether by way of flesh or of milk supply. It was at once keenly disputed at the Congress, and that denial has now received the formal endorsement of the highest scientific authorities in the United Kingdom. In this place we do not propose to discuss the conclusions of their second interim report.

It may be briefly stated that the Commissioners have come to the unanimous conclusion that tuberculosis may be communicated to human beings by cow's milk. The direct practical application arising therefrom is inevitable, namely, that stringent measures must be taken to prevent the sale of milk from cows suffering from tuberculosis. This will mean a revolution in the vast interests, both in town and country, involved in the national milk supply. The excessive infantile death-rate that constitutes a standing reproach to our modern science and humanity is closely wrapped up in the prevention of tuberculosis. Parliament will doubtless proceed to act with little delay upon the findings of this report in the direction of the inspection of dairy farms and town byres with a view to the rigid exclusion of tuberculous cows. Similarly, steps will have to be taken to test and exclude contaminated milk. An enormous impetus will probably be given to the municipalisation of milk supplies, while the duties as well as the powers of medical officers of health will be greatly multiplied. One much-needed reform that will probably be forced upon the attention of legislators at an early date is the centralisation of county sanitary districts, and the co-operation of town and county areas, as well as the necessity of making the office of medical officer stable and permanent, in order to relieve him from the pressure of local influences. The present report is a model of clear and precise statement. "The milk coming from such a tuberculous cow," runs one sentence, "ought not to form part of human food, and indeed ought not to be used as food at all. . . . Our results clearly point to the necessity of measures more stringent than those at present enforced being taken to prevent the sale or the consumption of such milk." In many ways this bids fair to become one of the most important public health documents ever yet presented to the world.

CURRENT TOPICS.

Proposed Charter of King Edward's Hospital Fund.

The extraordinary nature of the proposals contained in the Bill to confer a charter upon King Edward VII. Hospital Fund was recently commented upon in our leading columns. The reactionary spirit shown by its promoters was freely criticised, and we stated our conviction that no satisfactory administration of the funds of the medical charities could be hoped for except on the basis of democratic, or, at least, of representative—government. A great trust fund of this kind should be controlled by elected representatives of all interests concerned. The public, the medical profession, the medical charities, great and small, and the working classes should be adequately represented as well as large hospitals, the higher consultant ranks, professional philanthropists and other prominent public men. Can it be possible that King Edward's executive will ignore the recommendation of the Lords' Committee for a Central Hospital Board to be purely representative, that is, elected by various bodies. Thence is a far cry from the proposal to vest absolutely autocratic powers in the hands of a president. As a hint of the way in which such an action is likely to be viewed by the profession, we append a quotation sent us by an eminent London surgeon as illustrative of the injustice attached to civil autocracy:

> "The career of Amurath is a memorable proof of how perilously the possession of unlimited power tempts, first, to excessive severity for real wrongs—next, to ruthless haste in punishing for imaginary offences—and, finally, to the practise of inhuman cruelty on the slightest suspicion or vexation. The earliest executions which Amurath ordered, when he assumed independent power, were those of traitors and mutineers, whose guilt was as heinous as it was unquestionable. His slaughters grew more sweeping; but still for a long time his cruelty was seldom or never awakened out of mere wantonness or caprice. It was against real or suspected state offenders that the Imperial manslayer exercised his terrible prerogative during the first two years of his actual sovereignty. But by degrees his temper grew more moody, and human life became as nothing in his eyes. When he rode forth, any unfortunate wretch who displeased him by crossing or impeding the road, was instantly put to death, and frequently fell pierced by an arrow from the gloomy despot's own bow. . . . He beheaded his chief musician for singing a Persian air, which he said was doing honour to the enemies of the empire. Many other acts of equal atrocity are recorded of him, and the number of those who died by his command is reckoned at 100,000." (*a*)

Medical Man or Matron.

An excellent example of the ignorance of hospital authorities with regard to the proper relative positions of medical men and nurses was revealed at a Liverpool Vestry meeting last week. The Vestry recently opened an infirmary in the neighbouring country for old and ailing people, among whom are a number of senile dements. This institution is known as Highfield Infirmary, and is under the supervision of a matron, with a resident medical officer on whom devolves none but purely medical duties. To everyone with knowledge of institution work, and to most people with common-sense, such a paradoxical arrangement conveys the knowledge of certain trouble. Nor has it been long in coming. The nurses, being under no obligation to the medical officer, have apparently been banding themselves together to defy him, after discovering that he had sufficient self-respect and strength of character not to fall in with their ideas of the "discipline" of the patients. On one occasion, it seems, the nurses wanted to reduce the diet of certain of the patients who had given them some offence, and in another to put one of these poor old creatures into a cold bath during the recent icy weather. Offended with Dr. Hastings' refusal to comply with these humane proposals, it is asserted they got up an agitation which, reaching the ears of the committee, produced the impression that Dr. Hastings was "not an

---

(*a*) "History of the Ottoman Turks." By Sir Edward Creasy, M.A.—Extract from Chapter XIII.

unqualified success." Consequently when a question of an increase in Dr. Hastings' salary came up, members opposed, it and fortunately a debate was thereby produced which revealed the state of affairs at the infirmary. We are glad to see that the increase was eventually granted, and that the committee are taking steps seriously to inquire into the nurses' conduct, which seems to have been unbecoming in the extreme, and it may be hoped that in the course of their inquiries they will find the necessity of radically altering the system of government of the infirmary. As one of the members appropriately remarked, "If they opened a school they would put a schoolmaster in charge, if they opened a church they would put a parson in charge, but they opened an infirmary and put a matron in charge." To put a man to serve under a woman is bad, to put a medical man to serve under a matron is not only folly, it is an insult.

A Curative Institute.

Our attention has been drawn to a newspaper advertisement of a "New Health Cure," which is stated to be "under medical specialist supervision," and "approved by the leaders of the English medical profession." Extracts are given of notices from various London newspapers. The treatment is said to be "highly beneficial" in cases of constipation, chest complaints, liver troubles, heart affections, locomotor ataxy, and spinal curvature." This conglomeration of complaints, which may obviously include many conditions of an extremely grave and incurable kind, lends the affair an air of quackery that no amount of mere specious protest can dissipate. We are told that "the Consulting Physician may be seen from 11 to 1, and 2 to 5, or at any time by appointment. There is no fee for consultation." Recently, we believe, a circular was issued by this trading association in the name of a duly qualified practitioner. Under these circumstances we think his anomalous position claims the immediate attention of the medical defence societies and of the General Medical Council. If a qualified man is paid a fixed salary in a business venture, he is surely committing much the same offence as the much reprobated officer to the medical aid association, only that in the institute case quoted the offence is aggravated by the advertisement.

Cardiff Surgeon's Case.

It is announced that notice has been served on the solicitor for the plaintiff to the effect that in the case, "Southern v. Lynn Thomas and Skyrme," the appeal which had been entered with a view to setting aside the verdict returned when the case was tried in London before Mr. Justice Bigham and a special jury will not be proceeded with. The judgment, therefore, stands. It will be remembered that the verdict was for £100 damages and costs. The amount of the latter was said at the time to be about £8,000.

PERSONAL.

Dr. T. Blair has been presented by the Wigan Medical Society with a silver sugar-basin shaped like a cradle to commemorate the fact of a son being born to him during his presidency of the Society.

Dr. H. H. Williams on retiring from practice at Wick, Gloucestershire, has been entertained to dinner and presented with a piece of plate by his friends and patients.

Dr. Fletcher Little has been appointed a Justice of the Peace for Marylebone.

Dr. A. H. Carter, senior honorary physician to the Queen's Hospital, has been compelled to resign that position on account of increasing professional work. Dr. Carter will continue to hold his position as Professor of Medicine in the University.

Dr. J. O'Dowd, Government Medical Officer, British Guiana, at present on leave of absence, has been granted an extension of three months from March 18th next.

Dr. J. E. Godfrey, Surgeon-General of British Guiana, has returned to the Colony and resumed duty.

Dr. C. E. Maguire, who has been acting as Senior Medical Officer of Fiji, has severed his connection with that Colony on accepting the appointment of Government Medical Officer for the Tongan Protectorate.

Mr. Priestley Smith had the honour of the Honorary Fellowship of the Royal College of Surgeons of Ireland conferred upon him on January 26th.

Dr. Josiah Court, who stood in the Unionist interest for North-East Derbyshire last week, was beaten by 729 votes only. At the General Election last year he failed by 1,762.

Dr. Charles E. Beevor is the Lettsomian Lecturer for this year at the Medical Society of London. His subject is the "Diagnosis and Localisation of Cerebral Tumours."

Mr. H. O. Pilkington, Medical Officer of Health for Preston, will read a paper on "The Reduction of Infantile Mortality without Municipal Milk Depôts," at the Society of Medical Officers of Health on February 8th.

Mr. E. Parker Young, the Master of the Society of Apothecaries, presided at the annual meeting of the After-Care Association yesterday afternoon.

Dr. Oliver Avison has received permission from the King to wear the insignia of the Fourth Class of the Order of the Tai-Keuk conferred on him by the Emperor of Korea.

Dr. R. M. Simon has been appointed an examiner in Medicine at the University of Cambridge.

Last week a handsome testimonial was presented to Mr. William Bunn on the occasion of his resignation from the post of Secretary of the Metropolitan Hospital Saturday Fund, after many years of faithful and successful service.

At the Manchester Royal Infirmary, Dr. G. E. Loveday, M.B., B.C. (Cantab.), M.R.C.S., etc., has been appointed director of the Clinical Laboratory; Mr. E. H. Cox, M.B., Ch.B. (Vict.) re-appointed Assistant Surgical Officer; Mr. W. E Rothwell, M.B., Ch.B. (Vict.) re-appointed Junior Anæsthetist; and Mr. A. E. Johnson, F.R.C.S., re-appointed Surgical Registrar.

A Clinical Lecture
ON
CHRONIC NON-SUPPURATIVE DISEASES OF THE MIDDLE EAR. (a)

By MACLEOD YEARSLEY, F.R.C.S.Eng.,

Senior Surgeon to the Royal Ear Hospital.

LECTURE II.

Gentlemen,—In our last lecture we considered the subject of hypertrophic catarrhal deafness in its clinical and pathological aspects. To-day we must turn our attention to its treatment. We may conveniently consider this under the heads of internal remedies, the restoration of the permeability of the Eustachian tubes, and the correction of abnormal conditions of the nose and post-nasal space.

One of the most valuable *Internal Remedies* is Strychnine. This must, however, be given in fairly large doses. It is useless to give it in the form of Easton's syrup or any similar preparation; it should be administered either as the B.P. Liquor or in tabloid form. Personally, I prefer to employ the latter, commencing with one tabloid of $^1/_{30}$ gr. three times daily, and increasing the dose by one tabloid *per diem* until the limit of tolerance is reached. If the Liquor is used, one can start with $^1/_{20}$ gr. or $^1/_{30}$ gr. thrice daily, and augment this dose by $^1/_{100}$ gr. to toleration, or until $^1/_{10}$ gr. or $^3/_{25}$ gr. is taken thrice daily. In many cases this treatment will add to the improvement in the hearing and diminish the tinnitus. Another valuable remedy for tinnitus is Dilute Hydrobromic Acid. It is especially useful when the noises are of a pulsating character, and may succeed when Strychnine fails. It requires to be given in doses of from dr. ss. to dr. j., or even dr. jss., and may be prescribed alone or in conjunction with Strychnine. Other useful remedies for noises are Valerian (in full doses of the Ammoniated tincture), Iron and Arsenic (in anæmic cases), and Carlsbad Salts (in gouty persons).

As regards the restoration of the permeability of the Eustachian tubes, inflation is one of the most valuable methods we possess in the treatment of deafness. For the reasons pointed out in my last lecture, I prefer to use the Eustachian catheter in nearly every case. Another method of inflation that I wish to speak of and to warn you against is *Auto-inflation*. Never teach your patients to inflate themselves, either by the Politzer bag, by Valsalva's method, or by means of any of the so-called Self-inflators. Patients invariably overdo it, and, finding that inflation improves them, they practise it continually until they have so overstretched their membranes that their hearing is made much worse by the lax membrane resting upon the inner tympanic wall and ossicles.

The frequency of the inflation is to some extent dependent upon the case and the progress of improvement. I wish, however, to impress upon you the fact that if you inflate a chronic case and then wait a week before you repeat the inflation you give the ear an opportunity to revert to its former condition, and your labour is Sisyphus-like in its having to start afresh at every application of the catheter. To get anything like a result, you must inflate daily, or, at any rate, every other day. By that means, you are able to get a little more improvement each day before the previous result has quite passed off. It is my practice to inflate daily for a fortnight, then every other day for a week, then twice a week, and so on until the fortnightly or monthly application of the catheter is sufficient to maintain the improvement obtained. In doubtful cases, do not give up hope until you have tried for at least a fortnight.

With inflation, the injection of various medicaments is often very useful. Of these, Parolein, with Iodine (½ per cent.), Menthol (1 per cent.), or Iodide of Potassium (gr. v. to the ounce), are the most valuable. They are used by putting one or two minims into the wide end of the catheter, and then inflating, when the effect of a fine spray is produced. These methods often act best when combined with massage.

When there is much stenosis of the Eustachian tube, the passage of the Eustachian bougie, already described, is very valuable.

In cases with much tinnitus, it is sometimes of advantage to administer, through the catheter, such vapours as ethyl chloride, ethyl iodide, acetic ether, or nascent chloride of ammonium.

A method of treatment which has been used recently, and with some success, is massage of the drum and ossicles. This may be done by means of the Pneumo-masseur of Delstanche, the Siegle speculum, the Pressure probe, or the Oto-masseur of Lake. Of all methods I prefer the latter as giving the best results in my own hands. In using it, it is necessary to bear in mind that rapidity of vibrations and shortness of stroke are the essentials.

Of operative treatment, mobilisation of the malleus, in fixation of that ossicle, is the most useful. It must be performed under gas and by means of a modified pressure probe.

Of other operations, such as incision of the posterior fold, exploratory tympanotomy, &c., I shall not speak. They are mostly disappointing, certainly still *sub judice*. It is probable that, in a certain number of cases (those in which there are definite adhesions binding down the ossicles, and the stapes in particular) exploratory tympanotomy might be attended with good results.

Upon the question of the correction of nasal and naso-pharyngeal conditions I shall not touch, as they will be adequately dealt with by a colleague in a future lecture.

(a) Being the second of two Post-Graduate Lectures delivered at the Royal Ear Hospital on December 13th, 1906, and January 3rd, 1907.

I now pass on to the consideration of the disease which has been termed

OTOSCLEROSIS.

This name is a misleading one, both pathologically and because it has resulted in a confusion between the disease under consideration and the post-catarrhal changes in chronic hypertrophic catarrh. The pathology of this malady, which is responsible for a number of cases of chronic incurable deafness, is not yet fully made out, but it is, apparently, a rarefying osteitis of the labyrinthine capsule, characterised by the fixation of the stapes by bone, the throwing out of osteophytes both extra- and intra-labyrinthine, and the occurrence of spots of osteoporosis in the labyrinthine capsule.

Its onset is usually very insidious. It affects women twice as often as men, and makes its appearance usually between the ages of twenty and thirty, although it may start between ten and twenty, or as late as between thirty and forty. In a certain number of cases it appears to be hereditary, and has been ascribed by some writers to hereditary syphilis. As might be expected in a disease so prominently affecting young women, anæmia plays a part in its origin. Pregnacy and parturition have a decided adverse influence upon the disease, although I myself am inclined to believe that it is the after-strain of lactation that is most to blame in the advance which occurs in this form of deafness at this period.

Owing to the fact that patients suffering from otosclerosis, or, as I prefer to call it, rarefying labyrinthitis, do not usually die of their disorder, the *pathology* of its earlier stages has not yet been worked out, owing to the scarcity of material. What work has been done on the subject has been on cases already far advanced in the condition. These show two distinct changes, the occurrence of patches of osteoporosis in the bony labyrinthine capsule, especially in the promontory, the modiolus, and the neighbourhood of the fenestræ; and the formation of intra- and extra-labyrinthine osteophytes, with bony anchylosis of the stapes. There is in the ligamentous attachment between the footplate of the stapes and the edge of the fenestra ovalis a tongue of cartilage, and in this disease it is this structure which ossifies and so anchors down the stapes. In advanced stages of the condition the intra-labyrinthine fluids become diminished, and may disappear.

You will see by what I have said how hopeless is the outlook as regards treatment.

The disease usually progresses steadily to an advanced degree of deafness, but this progress may intermit, so that the patient remains for some time stationary. Again, it may suddenly progress rapidly, a condition to which Politzer gave the name of "malignant sclerosis." It is impossible, in the present state of our knowledge, to say what cause influences its progress. A certain number of cases occur in childhood, usually associated with adenoids. These are the children who disappoint us after the removal of their post-nasal growths by not recovering their hearing.

The chief *symptoms* in rarefying labyrinthitis are deafness, tinnitus, and Paracusis Willisii. The deafness comes on very gradually, increases to a marked degree, and is uninfluenced by inflation (unless there is an admixture of hypertrophic catarrhal deafness). The tinnitus generally precedes the deafness, is usually of a hissing character, and becomes a matter of very great annoyance to the patient. It is, as a rule, referred to the head rather than the ears. Paracusis Willisii, which I told you was a comparatively late symptom in hypertrophic catarrh, coming on in the contracting and post-catarrhal stages, is a fairly early symptom in rarefying labyrinthitis.

As regards the *tuning fork tests*, the Rinne reaction is negative for both the C and C forks. In very early stages it may be negative for the lower fork only. Bone conduction is, in the early stages, increased. This is probably due to the irritation of the auditory nerve by the commencing process going on in the cochlea. Later, it becomes diminished. Gelle's test gives the negative reaction of a fixed stapes.

On examination, the menbrana tympani appears practically normal, and shows no signs of retraction. It may, however, be somewhat more transparent than usual. Over the region of the promontory (more rarely in the neighbourhood of the oval window) there appears, in the majority of cases, a very characteristic reddish blush, due to the osteitis going on in that region. The external meatus is usually dry and with a lack of ceruminous secretion. On inflation the Eustachian tubes, in uncomplicated cases, are either normally free or appear more than usually patulous. Further, the patient *hears* the inflation whilst he does not *feel* it.

The upper air passages do not as a rule show any specially typical changes. The nose has been described as abnormally patulous. Some observers have insisted that the disease is dependent upon Atrophic Rhinitis (Ozena), but I do not think this has been at all satisfactorily proved.

The *Prognosis* is extremely unfavourable. When we consider that the disease is as much intra-labyrinthine as middle-ear, it is very evident that no manipulations or applications directed to the tympanum can have very much effect. However, despite this somewhat hopeless prospect, a few words must be devoted to the question of *treatment*.

First and foremost, *do not* inflate these cases. Inflation does no good, often positive harm. The only instances in which inflation is permissible are those in which there are in addition chronic catarrhal changes. The catarrhal trouble may then be amenable to treatment without interference with the rarefying labyrinthitis. In pure, uncomplicated cases the only use that can be made of the catheter is for the injection of remedies into the middle ear. Occasionally, in early stages, the use in this way of gr. v. to the ounce of Iodide of Potassium in Parolein, or of a solution of Parolein with ½ per cent. of Iodine may be found of service. The only local treatment that seems to me to promise anything is otomassage. This should not, however, be used if the first application diminishes the hearing.

In a disease such as this, our best hope should lie in internal remedies. Of these Phosphorus has been stated to give good results. It is best given in a 10 per cent. solution, either in oil or in Mist. Amygdalæ, the dose being from 10m., increasing gradually to 45m., three times a day. This drug requires to be given cautiously, as it may cause gastric disturbances. Strychnine (in full doses), Iodide of Potassium (in doses of gr. iij. to v. thrice daily in plenty of water), and the Syrup of the Iodide of Iron have all had their advocates. From what I have already said, a special look-out should be kept for hereditary syphilis.

Various operations have been suggested, but if the pathology of rarefying osteitis of the labyrinth be considered, the futility of the radical mastoid (advocated by Malherbe) or of trephining the promontory will be only too obvious. Personally, I look upon this malady as something akin to a tropho-neurosis, and, until the true pathology of the disease be elucidated in its early stages, we cannot expect to find a treatment adequate to deal with it. Probably the treatment of the future will lie mostly in prevention.

NOTE.—*A Clinical Lecture by a well-known teacher appears in each number of this journal. The lecture for next week's issue will be by Sir Charles Ball, M.Ch., F.R.C.S.I. and Eng., Honorary Surgeon to His Majesty the King, Regius Professor of Surgery in the University of Dublin, &c., on "The Treatment of Malignant Gastric Ulcer."*

ORIGINAL PAPERS.

A POSSIBLE DANGER IN EXPLORATORY PUNCTURE OF THE CHEST.

By HUBERT ARMSTRONG, M.D. Vict., etc.,
Assistant Physician, Liverpool Infirmary for Children.

The operation of exploratory puncture of the chest is generally regarded as a very trivial one, and quite free from danger to the patient. Of course there is the obvious and easily avoidable danger of infecting the pleura with a dirty needle. Unskilfulness may lead to infection of the peritoneum from an empyema, by exploring too low or directing the needle obliquely downwards. Pneumothorax has resulted. Subcutaneous emphysema, also, has followed the withdrawal of the needle. But the particular danger of which I am speaking to-night is not one of faulty technique, nor is it one which can be absolutely avoided, except by the avoidance of the operation, because it cannot be entirely foreseen. Last session, in the discussion which followed Dr. Buchanan's paper on empyema, I remarked that when in doubt as to the diagnosis I never hesitated to make use of the exploring needle. During the recess I have encountered a case which has caused me to modify this view. Now while, if I were *certain*, I should have no hesitation and no fear in exploring to confirm the diagnosis, it is just in the doubtful case that I should take up the needle with some trepidation.

The relation of my case will explain the nature of the danger to which I refer.

On June 27th, 1905, Bertha M., æt. 2 years and 9 months, was sent to the Infirmary for Children by Dr. McCann for a diagnosis, and came under my notice. Dr. McCann gave the following history: "The child had measles three months ago, complicated by lobar pneumonia. I left town shortly after, and my *locum tenens* on my return stated that there was an empyema which necessitated operation. I could not satisfy myself on the point, and as the dulness had not cleared up I thought it better to have another opinion. I gave her drop doses of tincture of iodine, with five-drop doses of phosphoric acid and compound tincture of cinchona, which improved matters to a certain extent, but they have been at a standstill for some weeks." The girl was only seen by me in the out-patient department, and my notes are not very full, but I have the following:—

The child was thin and wasted, and rather fretful, with a hectic flush. Temperature 101°. The actual pulse and respiration rates were not recorded; both were accelerated, but maintained a normal ratio. No dyspnœa. On examination, the right side of the chest was dull posteriorly up to the spine of the scapula; there were bronchial breathing and increased vocal resonance all over this area, with loud inspiratory crepitations. Apex of the heart not displaced.

Upon these physical signs I was inclined to agree with Dr. McCann as to the absence of fluid; but the dulness being so absolute, bronchial breath sounds in empyema being so common in children, and empyema being the element it was desired to exclude, I felt justified in exploring. Consequently I made the usual exploratory puncture in the posterior axillary line just below the angle of the scapula. The result was exceedingly alarming. The child gave a gasp, and then began to cough, bringing up a quantity of frothy mucus freely stained with blood. At the same time she became pallid and broke into a profuse sweat; the pulse failed, the facial expression took that "far-away" look characteristic of impending dissolution, and for some minutes I could not disguise from myself that the condition was extremely critical. However, stimulants being administered, the cough stopped after a little, and the patient gradually revived, and later in the afternoon was able to be taken home. If the evidence of the hæmoptysis had been wanting, the needle was *felt* to have entered the lung, being moved through a considerable angle by the first gasp. The piston was drawn and the needle removed almost simultaneously and at once, and nothing but a little blood was obtained either in the syringe or the lumen of the needle. The diagnosis made was chronic interstitial pneumonia, possibly infected with tubercle. The after-history of the case has many points of interest, but I only make use of that portion which illustrates my subject.

I consider myself fortunate that the patient did not die on the spot, for such a catastrophe has since formed the subject of a paper and discussion at a meeting of the Society for the Study of Disease in Children, and several other fatalities have been recorded. Carpenter (1) reported the first in 1893, Russell (2) one in 1898, Oliver (3) one in 1904, another was published by Fortescue-Brickdale (4) in 1904, while two more are related in the current volume of the *British Journal of Children's Diseases* (5). In all these cases the amount of hæmorrhage varied, but the symptoms were similar to those I have described in my patient, only that death ensued within a few minutes instead of recovery. Other cases have been described in which death did not occur until some hours or days after the exploration, although the alarming symptoms dated from the moment of operation. Six out of nine collected fatalities occurred in children under eight.

In all cases the danger seems to lie in the puncture of chronically inflamed lung-tissue, and to be non-existent when fluid is present provided the needle does not pass through this and strike diseased lung beyond.

In 1900 Dr. McAlister read a paper here in which he advocated puncture of the lung in chronic pneumonic conditions as a therapeutic measure "which" (I quote the report in the *Liverpool Medico-Chirurgical Journal* (6)) "can certainly do *no* harm, and may be followed by beneficial results." I do not know whether he still advocates this practice, but in view of these reported fatalities it would appear that the benefits, which I confess I think I have seen myself in some cases, are purchased at what must now be considered a by no means negligible risk.

As to the cause of the syncope. In some of the recorded cases it has been attributable to hæmorrhage, both directly—a large quantity of swallowed blood having been found in the stomach—and indirectly, from asphixiation by the bleeding into the lung and air-passages. In others it is ascribed to irritation of the terminal filaments of the pulmonary vagus, leading to reflex inhibition of the vital centres in the medulla, and vaso-motor disturbances producing œdema of the lungs, with the expectoration of the frothy mucus. Into others both these elements may enter. Obviously there is something more here than mere faintness at the momentary pain of the prick, or fright at the sight of the blood. My patient was not coughing before the operation, and certainly the quantity of watery mucus she brought up was not what one would have expected from the signs in the chest, while she was collapsed before the blood had reached the mouth and become visible. The symptoms resemble those described as the result of a sword-thrust into the lung; but an exploring needle is not to be compared with a rapier, and as it is used over and over again without bad results in such cases as I have described, there must be some personal element involved, in addition to a hyper-excitability of the pneumogastric which may be presumed to originate in the pneumonic condition.

Treatment.—It would be as well, when about to explore a doubtful case, to fortify the patient by the previous administration of such stimulants --alcoholic or otherwise—as you pin your faith to, to perform the operation in the recumbent position, and not to plunge the needle too far in. If, after that, syncope threatens, artificial breathing should be tried, unless there is hæmorrhage as well. In the latter case it is hard to see what can be done with advantage.

No doubt this is a rare accident, but there can also be no doubt now that puncture of a lung in a state of chronic inflammation involves a danger deserving of recognition, and that we should learn not to depend too much on the results of exploration, but rather to cultivate the safer and sounder method of the correct interpretation of physical signs.

ON TUBERCULOSIS DISPENSARIES AND THE CO-ORDINATION OF MEASURES AGAINST TUBERCULOSIS. (a)

By R. W. PHILIP, M.A., M.D., F.R.S.E., F.R.C.P.
Physician to the Royal Infirmary, Edinburgh, and to the Royal Victoria Hospital for Consumption.

THE tuberculosis dispensary as a factor in the campaign against tuberculosis is no longer on its trial. In any complete organisation against tuberculosis the dispensary will be found to play a most important part. This has been my belief for the past 20 years. It was this that led to the foundation by me in 1887 of the Victoria Dispensary for Consumption in Edinburgh. The practical value of what was then an *a priori* conception has been firmly established during the development of operations. Increasing familiarity with the idea has led to a widespread recognition of the significance of the dispensary. More recently the rapid and apparently independent erection of similar institutions in Belgium, France, and Germany has been remarkable.

CONCEPTION OF THE TUBERCULOSIS DISPENSARY.

The *motif* for the establishment of the Victoria Dispensary in 1887 was the query: What practical value had accrued to the community, as a community, by Koch's discovery of the tubercle bacillus? If the community, as such, was to benefit practically by the discovery, there appeared to be need of centralised effort in order to ascertain the extent of tuberculosis in a district, and to devise means for its limitation and prevention.

To meet this indication, the method of treatment which was then in vogue in hospitals was useless. The amelioration, or even cure, of a certain number of cases of tuberculosis could do little to affect the wider issue. The formation of a central institution or dispensary, to which persons of the poorer classes affected by tuberculosis should be invited or directed, seemed to offer the basis of a completer solution. Thereby access would be readily obtained to the foci of disease, not merely in the affected individual under examination, but also in other members of the same household and in affected dwellings.

FUNCTIONS OF A TUBERCULOSIS DISPENSARY.

The tuberculosis dispensary should be, for every city or district, the uniting point of all other agencies. It should not be an isolated institution, but form an integral part, indeed the centre, of a great network of operations. To the dispensary tuberculous patients of the poorer classes, and hospital patients with chronic colds or phthisis or persistent ill-health, should be invited. Tuberculous patients presenting themselves at infirmaries, hospitals, and other charitable institutions should be directed to the tuberculosis dispensary. Employers of labour and heads of public works should be apprised of the existence of the dispensary, so that invalid employés may be directed thither. The public should be made aware that the dispensary is prepared to answer all inquiries regarding tuberculosis, and to advise, in a given case, what is best to be done. The dispensary should constitute a centre for the dissemination, in the widest fashion, of information regarding prevention and treatment.

THE ROYAL VICTORIA DISPENSARY FOR CONSUMPTION, EDINBURGH.

The programme of the Royal Victoria Dispensary was as follows:—1. The reception and examination of patients at the dispensary; the keeping a full record of every case, with an account of the patient's illness, history, surroundings and present condition and progress. 2. The bacteriological examination of sputum, etc. 3. The instruction of patients how to treat themselves and to minimise the risk of infection to others. 4. The dispensing of necessary medicines, sputum bottles, disinfectants, and—where the patient's condition seemed to warrant it—foodstuffs and the like.

(a) Being Introduction to a discussion on Tuberculosis Dispensaries at the International Conference on Tuberculosis held at the Hague, September 5-8 1906.

5. The visitation of patients at their own homes by (1) a qualified medical man, and (2) a specially trained nurse, for the double purpose of treatment and of investigation into the state of the dwellings, the general conditions of life and the risk of infection to others. 6. The selection of more likely patients for hospital treatment, either of early cases for sanatoria, or of late cases for incurable homes, and the supervision, when necessary, of patients after discharge from hospital. 7. The guidance generally of tuberculous patients and their friends on every question concerning tuberculosis.

The premises of the Victoria Dispensary as at present arranged contain:—Two consulting rooms, a laryngoscopic room, one large waiting room, two dressing rooms (male, female), a general office where names are entered, a laboratory for bacteriological examinations, a drug and food store. The dispensary is open thrice weekly for three or four hours, the staff consisting of—

(1) Four qualified physicians (three honorary) who attend for the purpose of examining and instructing patients. (2) One of the medical officers receives a salary of £60 a year and devotes a large amount of time to the work. In addition to examining patients at the institution, along with the honorary physicians, he pays domiciliary visits to the dwellings of patients, in co-operation with the trained nurse. He makes bacteriological examinations of expectoration and other discharges. By arrangement with the city authorities, he notifies all cases of tuberculosis which he meets. He advises regarding the disinfection of houses during illness, and after the removal or death of the patient. He supervises treatment of patients at their own home when this is desirable. He selects suitable patients for the sanatorium. In co-operation with the city authorities, he drafts the more advanced or dying patients to a hospital now dedicated to such cases in the neighbourhood of the city.

(3) A nurse who has been carefully trained in modern open-air methods at the Royal Victoria Hospital for Consumption, Edinburgh, the sanatorium in connection with the dispensary, visits the homes of the patients. She readily wins their confidence by her interest in their welfare. She instructs the patients or their friends (wives, mothers, etc.) both as to treatment and prevention. In co-operation with the visiting physician she reports regarding the patients' residence and other conditions according to the annexed schedule of inquiry. The reports, when completed, are vouched for by the signature of doctor and nurse.

SCHEDULE OF INQUIRY REGARDING DISPENSARY PATIENTS.

No. in ledger......... Date of report........... Name? Age? Address? Married or single? Occupation? Has patient changed occupation? Able to work full time? Or part time? If unable, confined to bed? How long ill? Situation of house (area, ground floor, first, etc.)? Number and ages of inmates? Number and description of rooms? General aspect of house (clean, damp, dusty, smelly)? Number of windows? Can they open? Are they kept open (a) by day? (b) by night? Have they always been kept open? Does patient sleep alone (a) in bed? (b) in room? How is washing of clothes done? How long in present house? If has moved within two years, previous addresses? Have there been illnesses or deaths in house (a) in own time? (b) in previous occupancy? Exposed to infection (a) at home? (b) at work? (c) among friends? Present health of other members of household? What precautions taken to disinfect? T. B. in sputum? T. B. in dust of room? General dietary? Teetotal? General condition (well-to-do, badly off)? Proximate income of household? Assisted by societies, church, friends, rates?

Signed .... Reporter.
.... Medical Officer.
(Signed by doctor and nurse.)

(4) A volunteer Samaritan committee of ladies, in conference with the doctors, take charge of more distressing cases, where through prolonged illness the financial conditions have been much reduced.

(5) An officer—a working man who gives his entire time to the dispensary—lives on the premises. The man receives and enters the names of the patients on the afternoons when the dispensary is open. When the dispensary is not formally open, he attends to requests from patients or other persons. The officer is conversant with the home and work conditions of many of the patients, and is a valuable lieutenant both to the doctors and nurses.

RESULTS OF DISPENSARY OPERATIONS.

The organisation of the dispensary is thorough. Each part of the system is closely related to the rest, so that a large amount of work is expeditiously and inexpensively overtaken. From first to last we have found no difficulty whatsoever in relation to the nurse's house-to-house visits. On the contrary, these have been most gladly welcomed by all types of patients, and her inquiries willingly answered. There can be no doubt that the system of domiciliary visitation by a specially trained nurse, in co-operation with the doctor, has been a sanitary agent of great importance to the city of Edinburgh.

From my experience of the satisfactory way in which the work of investigation and general guidance is effected by the nurse, who herself has been most carefully trained in methods for the prevention and treatment of tuberculosis. I should be unwilling to replace her services by those of the so-called working man *enquêteur* as recently recommended in France and Belgium.

The dispensary's programme has been successfully carried out by the staff during the past 19 years. During each year some 17,000 attendances have been registered. As many as 87 individual patients have been received in one day. About 1,000 reports are made annually regarding the home conditions of patients, and about as many notifications have been made to the city authorities.

By means of the systematic record of the home conditions according to the schedule referred to, there has been accumulated a great mass of valuable statistics and information regarding the incidence of the disease in the district. These are continually added to from day to day.

An analysis of these records has yielded facts of the greatest importance. Thus there has been illustrated the extreme frequency of tuberculous disease in children and in housewives. A map of the city has been made showing the frequency of the disease in certain houses and streets. Proof has been obtained of its occurrence, along with various insanitary conditions of dwellings (insufficient air, absence of sunlight, etc.), and the attention of the authorities has been drawn to the fact. The reports show the frequency with which one or more persons share a room, or even a bed, with the consumptive patient. Particular attention has been paid to such cases, either by removal of the affected patient (a) to a sanatorium, or (b) to a hospital for dying cases, or by removal of unaffected members of the household to healthier surroundings. One of the doctor's duties in such circumstances is to examine into the health of other members of the family. It is remarkable how frequently two, three, or even more persons, not previously suspected, have thus been shown to be tuberculous. Another important point has emerged—viz., the frequency with which the tuberculous patient, from one cause or another—often from financial reasons—changes his house. By this means infected areas become quickly multiplied. The records also show the absence—apart from the interference of the dispensary—of precautions with a view to disinfection. Now happily, by arrangement with the city authorities, the dwellings of such patients are thoroughly disinfected at the city expense.

It has been sometimes maintained that such a dispensary is impracticable, as running counter to the interests of, and therefore likely to be opposed by, the medical practitioners of the place. This has not been the experience of the Victoria Dispensary, either with medical men or medical charities.

It should be clearly understood that a dispensary such as this is a much more elaborate institution than exists in relation to the out-patient departments of consumption or other hospitals. The latter doubtless do excellent work, so far as their resources allow. Their effort is, however, primarily directed towards the treatment of the individual patient, and little attention is extended to the wider aspect of the tuberculosis problem.

MAINTENANCE AND DEVELOPMENT OF DISPENSARY.

This sketch of the operations of the Royal Victoria Dispensary during the 19 years of its existence and development may serve to illustrate the important part played by a well-organised dispensary in any complete movement against tuberculosis. It will be found desirable that operations should extend on all the lines I have indicated. The dispensary should be in closest relationship with sanatoria for early cases, and with hospitals for dying cases. Thus the Victoria Dispensary has established as sanatorium the Royal Victoria Hospital, with accommodation for 80 patients, and has relationship, through co-operation with the city authorities, with a hospital for dying cases, with accommodation for 50 persons.

As to maintenance, a further question presents itself. Having regard to the extent of the issue, we cannot afford to trust to individual effort, or even to wider benevolent enterprise.

On whom, then, should fall the responsibility for such an organisation? The answer seems to be clearly —on the local authorities, municipalities, parish councils, boards of guardians, and the corresponding bodies in different countries. In our cities the institution should be municipal. Experience in the foundation and development of the Royal Victoria Dispensary has satisfied me that the extensive ramifications of the disease demand that the central dispensary as a base of operations should be maintained by the local authorities. Local authorities ought to possess the information regarding tuberculosis which a well-planned dispensary is calculated to yield.

The dispensary should be placed under the direction of the Medical Officer of Health. It should, however, form a separate and well-defined department of his activity.

The actual cost of the Royal Victoria Dispensary is approximately £500 per annum. This is a small sum having regard to the extent of the operations. The advantages accruing to the community are incalculable, and should thoroughly justify the discharge of public money for the purpose. Seldom does expenditure by local authorities promise such certainty of satisfactory return.

So far as Scotland is concerned, a rapid advance has been made. Every year the extent of operations of the Victoria Dispensary has steadily increased. Several towns and districts of Scotland have awakened to the large sphere of work which is compassable only by such an institution as the tuberculosis dispensary. Still more recently the Local Government Board of Scotland has emphasised in the strongest way the significance of the dispensary as an element in the administrative control of pulmonary tuberculosis, and has strongly recommended local authorities to institute similar dispensaries.

ORGANISATION AND CO-ORDINATION OF MEASURES AGAINST TUBERCULOSIS.

Much is to be gained by uniformity of action in such a campaign. Deeply impressed with this, I venture to reiterate what I have frequently had occasion to propose as a scheme of organised and co-ordinated operations against tuberculosis which might be uniformly followed in our larger centres. The organisation, which implies notification in one or other form, should include:—

(1) A tuberculosis dispensary with the functions and relations I have attempted to outline.

(2) A hospital or asylum for dying patients, chiefly in the interest of other persons.

(3) A sanatorium or sanatoria for selected patients who, with a view to cure of the disease, require a special *régime* not procurable at their own homes.

(4) Colonies for the after-life and supervision of patients in whom the disease has been arrested, so as to make selected open-air employment feasible and desirable.

The various departments should be intimately connected and co-ordinated. They will each be more serviceable the more closely they are thus related. Each department is of value itself, and each has its own sphere of operations. The key to complete success in the campaign against tuberculosis lies in well-adjusted co-ordination of the several departments.

Every step in the gradual development of the Edinburgh scheme during 19 years has strengthened my belief in the efficacy of the tuberculosis dispensary as a base for further operations. In this belief I recommend to every considerable community the establishment of such an institution which will serve at once as a developmental centre and uniting point of other agencies.

It seems to me, indeed, difficult to over-estimate the value of the dispensary as an instrument of preventive medicine, whether as a bureau for receipt and distribution of information and assistance, or as a clearing-house in respect of the vast amount of tuberculous material with which every community will find itself called upon to deal.

CLINICAL RECORDS.

AN EARLY CASE OF LEONTIASIS OSSEA. (a)

By S. HORACE LAW, M.D.,
Surgeon to the Dublin Throat and Ear Hospital, and Throat Surgeon to the Adelaide Hospital, &c.

PATIENT, J. J., æt. 12, male. This condition was first described by Verchow, and named leontiasis ossea by him. The number of cases reported are few, the majority of which were found post-mortem in the dissecting-room, etc., and while the condition is mentioned in most text-books, little is said beyond referring back to the classical case of Verchow.

In looking at this case, one might almost think that it was the original one described, so great is the similarity. The chief points of interest are as follows:—When first seen, some four years ago, by me, the condition of swelling was much less marked, and I did not think that it was pathological, though I distinctly remember being struck by the bilateral enlargement on each side of the nasal processes of the superior maxillæ. He then complained of nasal obstruction, and the removal of adenoids gave him relief, though not for long. I saw him once or twice since then, but the peculiar enlargement did not strike me until this last occasion (November, 1906), when the growth had become marked.

The condition found is as follows:—

The patient is a small boy for his age, which is 12, but upright and sturdy. He seems strong and in good general health, and his only complaint is nasal obstruction, and that was what brought him to me.

On examination a hard, bilateral growth is seen in infra-orbital region, extending up in such a way as to cause the eyes to be pushed outwards, and also to bring about exophthalmos.

The lateral walls of the nose are pushed towards the middle line, so as to occlude the nostrils, though a probe can be passed up to the sphenoid, etc., and air can be blown through nose.

The naso-pharynx is not involved.

The pharynx and palate are normal.

The antra of Highmore are dark to transillumination, and when I passed an ordinary antrum drill in through the canine fossa on the right side, I failed to reach a cavity, though I went in about an inch in two directions.

The bone was soft and spongy. One may therefore conclude that there are two large osseous masses lying on either side in the infra-orbital regions, filling both antra, and extending in various directions, as mentioned above.

Incidentally, he has dacryo-cystitis on both sides.

X-ray photographs show dense shadows corresponding to the obvious growths, and especially I would mention the shadow of the growth lying between the orbits, and the fact that the cranial vault of this child is about the same thickness as one would expect to find in an adult.

(a) Read at the Surgical Section of the Royal Academy of Medicine in Ireland.

I have ventured to call my case by this classical name, leontiasis ossea, and if one compares it with the case originally described by Verchow, in his "Pathologie des Tumeurs," 1869, Vol. II., page 21, which was under the care of Forcard, one sees that it agrees very nearly with it. It commences in early life. My patient was 8 at the time I first saw him. Forcard's was 12. But, from the description of his case, undoubtedly the condition had existed for some little time previously.

My case has suppuration in the lachrymal sacs. as also, apparently, had the other; though this, of course, is merely a coincidence. The development has been very slow—so slow, in fact, that it would be almost impossible to measure it, though, after the lapse of a few years, the contrast is distinct and unmistakable.

Nearly all writers on surgery refer to this disease. Von Bergmann, in his "System of Surgery," Vol. I., gives an exact account, and two woodcuts, both of which show the advanced stage of the disease. He mentions the specimen (also mentioned by Verchow) in Dupuytren's Museum. I have not been able to form any idea as to how many cases have been described, as, though most books mention it, they rather take up the historic case, and do not describe actual cases seen. Looking back in the *British Medical Journal* for 10 years, I found three cases recorded. The first, in Vol. I., 1898, page 1,392, is described by Dr. Churton, and seems very similar to my own, except that the child showed more symptoms of rickets; and the second, in Vol. I., 1900, page 1,230, is recorded by Dr. Stephenson, and he describes the growth as beginning in the lower jaw. The third, in Vol. II., 1901, page 1,341, is described by Mr. Robinson as a fairly typical case. Unfortunately, some works do not seem to have differentiated between ostitis deformans and this condition. Suffice it to say that in ostitis deformans the long bones are first affected, and then the skull, and the disease is limited to the head, and, in the condition before us, the face is the first to be affected. Also, ostitis deformans commences in adult life; leontiasis ossea in childhood. Again, others have included it under tumours of the nasal processes. One picture, which I have found in two or three text-books, quoted as after Hutchinson, is called symmetrical osteomata of the nasal processes of maxillæ, and presents most clearly the same facial aspect as is seen in my case, the only difference being that, apparently, it was in a grown-up man. One other condition mentioned by Bland Sutton in his book on "Tumours," page 43, is worthy of comparison—namely, that many of the negroes on the West Coast of Africa present symmetrical exostosis of the infra-orbital region; but there the similarity ends, as the deeper enlargement is absent, nor is there any thickening of the cranium.

Syphilitic hyper-osteosis of the skull and face might occasion some difficulty in diagnosis, but they are never so uniform and so symmetrical, and the other symptoms of the disease would probably clear the matter up.

Again, acromegaly always begins at the epiphyses of the bones of the lower and upper extremities, and this would enable the differentiation to be easily made. The differential diagnosis between simple osteomata and this condition of hyper-osteosis should not, as a rule, present much difficulty. The age, the symmetry, the comparative painlessness, the cessation of growth in the earlier part affected, and the taking on of new growth in other parts of the face and skull, should render the differential diagnosis clear. It is quite clear that neither syphilis nor injury can be ascribed as a cause of this very typical disease, and no treatment seems to be of any avail. Surgical methods are obviously impossible, and the administration of mercury or iodide of potash does not seem to have influenced it one way or the other.

The prognosis is nothing short of lamentable. One can only expect slow advance in the portions now affected, then the cessation of growth there, and the commencement of thickening in the other parts of the skull, till finally, often at the age of 35 to 40, the gradual pressure on the brain gives rise to dementia and death.

THE OUT-PATIENTS' ROOM.

KING'S COLLEGE HOSPITAL.

Sinuses due to foreign bodies.

By PEYTON BEALE, F.R.C.S.

AMONGST the out-patients was a man, æt. about 21, complaining of a discharge of pus from a small sinus about half an inch to the left of the anus. The patient's history was rather vague, and at first sight not very much to the point, for about fourteen or fifteen years ago he had suffered from some very extensive suppuration apparently in the upper part of the abdomen. On examining his chest he was found to have a scar just below the angle of his right scapula; the scar looked a very old one, and the man could give no account of it, but from its position it was fairly obviously the result of an operation for empyæma, probably performed when the patient was four or five years old. He could give very little account of the abscess in the upper part of his abdomen, for he was treated at a provincial hospital, but he remembered that three or four incisions were made in the right loin, that drainage tubes were used for some weeks, and then that the incisions healed up. Ever since he had had more or less discomfort in the region of the right loin, never any really acute pain. About three weeks ago he had a severe pain on defæcation about the anus, and then noticed that he had a hard lump on one side of it; he poulticed this and it burst, discharging a good deal of pus, and it had continually discharged until the present time. On examining the sinus with a probe dipped in pure carbolic acid, a hard body was found about half an inch beneath the skin; it was movable and felt like hard bone. The skin over the sinus was painted with pure carbolic to render it anæsthetic, and was cut with a pair of scissors for about a quarter of an inch away from the anus; on introducing a pair of forceps, a piece of bone was easily removed; this bone was found to be about a quarter of an inch of rib, corresponding in size to that which one would expect in a child about four years of age. The history of the case, Mr. Beale said, was probably as follows: when about four years old the patient was operated upon for an empyæma; the surgeon no doubt excised a piece of rib, and finding he had not a sufficiently large opening, cut off another small piece about a quarter of an inch long; this no doubt fell to the bottom of the pleural cavity, where it must have remained for some years. By a slow process of ulceration it must then have penetrated the pleura and caused an abscess in connection with the diaphragm; this no doubt became a subphrenic abscess. The piece of rib must then have got down by one of the crura of the diaphragm and passed along the sheath of one of the posterior abdominal muscles, possibly the quadratus lumborum, then it must have made its way down into the pelvis behind the peritoneum until it reached the ischio-rectal fossa, where it formed an abscess which burst as described. Mr. Beale remarked that he had never come across a case similar to this, but he had removed from the pleural cavity a piece of rib which had slipped in and been lost, as the result of an operation for empyæma seven or eight years previously, but this had caused a sinus in the chest wall at the seat of operation to remain open continuously. In this case he was struck by the fact that the piece of rib had undergone no change except in colour, which was grey; in shape, and as regards its edges it looked exactly as if it had been recently cut with a pair of sharp bone forceps. He had come across several cases of ischio-rectal and perineal abscesses and persistent sinuses which, when opened up, were found to contain pieces of rubber drainage tube, and it was, he thought, a remarkable fact how these came to be left *in situ* for so long a time; he believed the explanation was that the patient went from one surgeon to another, and when an exploratory operation was advised it was again and again refused.

OPERATING THEATRES.

MIDDLESEX HOSPITAL.

Operation for Wiring Fractured Patella.—Mr. **John Murray** operated on a man, æt. 30, who had been admitted four days previously for a transverse fracture of right patella. The history was that the patient was carrying a sack of coals into a house, when he tripped against a piece of wood and fell heavily to the ground. On admission the right patella was found to be fractured transversely near the centre. There was three-quarters of an inch separation between the fragments, and a great deal of swelling of the joint, which was distended with fluid. There was also a good amount of ecchymosis of the soft parts. The limb was placed on a back splint, and an ice-bag applied. At the operation four days later an elliptical incision with the convexity outwards was made over the knee, and on reflecting the flap thus formed the fracture was exposed. A quantity of bloodclot filling the joint and extending between the fractured surfaces was removed, and the fibrous tissue, the remains of the torn quadriceps extensor tendon, which overlapped the edges of the fractured surfaces, was carefully separated so as to allow the surfaces to come into contact. Each fragment was drilled with a bradawl, and a silver wire passed with which the fragments were accurately approximated. A few silk sutures were inserted so as to bring the torn ends of quadriceps extensor together. The skin was sutured and dressings applied, the limb being placed on a back splint. Mr. Murray said that he preferred the open operation to any form of subcutaneous suture. He thought there was no doubt that failure to obtain bony union was due to the overlapping of the torn quadriceps extensor tendon, which invariably covered the fractured surfaces and effectually prevented the fragments from being brought into immediate apposition, and that it was only by the open method—that is, by an open operation—this fibrous tissue could be removed from between the fragments. The first essential for the success of the operation was, he considered, the thorough cleansing of the skin, and this he always gave instructions to be carefully carried out for at least two days previous to the operation. Another advantage of postponing the operation for a few days after the accident was, he said, that there was less tendency for subsequent effusion into the joint to occur. With regard to the incision, provided it was not made directly over the centre of the patella, he did not think the direction of the convexity was a matter of great importance. It was, of course, necessary to carefully remove all bloodclot, and more particularly to displace the fibrous tissue from between the fragments; the advantage of not removing this fibrous tissue was that it forms a covering for the wire. With reference to drilling the bone, he pointed out that the first fragment was drilled from without inwards, and the second from within outwards; by so doing the drill-holes could be made to correspond accurately. He thought that in cases of operation on the knee-joint, if strong antiseptic lotions were used there was much greater tendency for subsequent effusion to take place. Therefore he preferred to employ normal saline solution or boiled water for instruments and dabs, and also for the operation wound. With regard to the application of a splint, one was merely put on, he remarked, to restrain movement whilst the patient was recovering from the anæsthetic, and it would be removed on the following day.

A fortnight after operation the wound was healed, the patient could flex his knee through 45 deg., and was to get up in a few days.

TRANSACTIONS OF SOCIETIES.

OPHTHALMOLOGICAL SOCIETY OF THE UNITED KINGDOM.

Meeting held Thursday, January 3rd, 1907.

The President, Mr. Priestly Smith, F.R.C.S., in the Chair.

Mr. **Simeon Snell** (Sheffield) related a case of TUBERCLE FILLING THE EYEBALL, in which the opsonic index was regularly taken. The patient was a boy, æt. 12. Before coming under Mr. Snell's care in April, 1906, he had been under surgical treatment for tubercular abscesses in the arm and leg. At the time when he was seen the sight of the left eye had begun to fail four months before, and then the left eye was prominent and apparently slightly larger than normal; the conjunctiva was injected, but there was no pain. Vision was lost. The interior of the eye was occupied by a mass of yellowish-grey material, on which retinal vessels were seen. Tubercle of the choroid and vitreous was diagnosed. Immediate enucleation was decided against. A little later the eye became inflamed and painful, its tension was raised, and its size increased, and the interior became more filled up. Tuberculin injections were then tried, and the opsonic index was regularly taken. Tuberculin injections of 1/800 m.g. were twice given. The boy greatly benefited, the eye became smaller, and the mass in the interior was thought to be caseating. The eye was removed on September 17th, by which time it was no larger than normal. The boy did perfectly well after the operation. Examination of the globe showed it to be tubercular, but bacilli were not found. The choroid was the structure most affected.

Mr. **Snell** also related particulars of a family several of whom had suffered from "Nyctalopia." The earliest ancestor who suffered was the patient's grandmother. Information was obtained of 63 of her descendants, extending to the fourth generation. Out of 64, 12 were affected with nyctalopia, 9 being males and 3 females.

A peculiar feature was that the males had girls affected and boys healthy, and the females had boys affected and girls healthy.

Mr. **Arnold Lawson** related two cases of acute STREPTOCOCCIC INFECTION OF THE CONJUNCTIVA.

Case I. occurred in a child 16 days after birth. At first there was some swelling of the lids and a muco-purulent discharge. After 10 days the cornea became infiltrated, and the case ran a rapid and acute course. A tough conjunctival membrane developed, and within 36 hours of the first affection of the corneæ the sight was hopelessly destroyed. The general health was not affected. Swabs taken from the conjunctiva showed almost pure cultures of streptococcus pyogenes. Mr. Lawson did not see the case until the corneæ were infiltrated, and nothing seemed of any avail in allaying the course of the disease.

Case 2 occurred in a child convalescing from scarlet fever, who was then attacked with measles. Ten days later the temperature was high and fluctuating, as seen in pyæmia; at the same time brawny swelling of the lids commenced. After a few days the discharge increased rapidly, and the corneæ became suddenly infiltrated, and within 24 hours the condition was hopeless, and palpebral and ocular conjunctivæ of both eyes was covered with a dense yellow tenacious membrane. The child was exceedingly ill, and recovery was doubtful. The sloughs eventually separated, but the cicatricial contraction of the conjunctiva was very severe. The infection was a mixed one, due to staphylococcus pyogenes aureus and streptococcus pyogenes. The contraction in both cases was very severe, and in neither case did treatment seem of the slightest avail in arresting the course of the disease.

Mr. **Brooksbank James** read some notes on

STEREOSCOPIC VISION.

He remarked that most experiments which had been carried out had been conducted at comparatively short distances. He described an apparatus which he had introduced in order that the same may be estimated at the usual testing distance of, say, 6 metres. The apparatus was simple and at the same time most delicate in the estimation of the third dimension. It consisted of a box in which only the floor and end walls remained, the sides and roof having been removed. In the front wall was an oval aperture in its centre. At each side was an electric lamp which illuminated the interior; the front and back walls were covered with black velvet. The floor was pierced with numerous round holes, each separated by an interval of about an inch. The test objects were white painted sticks of different sizes, and they were long enough for each extremity to be hidden behind the margin of the aperture in the front wall of the instrument when placed upright in the holes. In this way it was found impossible for a person using one eye only to tell whether one stick was in front of the other; they always appeared to be in the same plane. The apparatus could, of course, be used at any distance, and it afforded a convenient way of ascertaining the quality of the stereoscopic vision in cases of partial amblyopia of one eye.

Mr. James alluded to the theories held with regard to the estimation of the sense of depth, and also to the importance of recognising the several grades into which binocular vision can be divided.

ROYAL ACADEMY OF MEDICINE IN IRELAND.

Section of Surgery.

Meeting held Friday, January 11, 1907.

The President, Mr. H. R. Swanzy, in the Chair.

SOME POINTS IN THE TREATMENT OF ENLARGED PROSTATE.

Mr. L. G. **Gunn** made a communication on the above subject. He thought that too much attention was paid to the operative treatment of this affection. As many cases can be greatly benefited, though not cured, by non-operative treatment, it is well to remember this before advising a patient to have the gland removed. Mr. Gunn then gave a brief account of work he had seen at Paris, London and Berlin. At the first city prostatectomy was hardly ever performed, at London it was always advised, while in Berlin palliative measures were often used. The speaker then gave in detail the lines on which he tried to carry out the treatment of such cases, giving a short account of 41 cases of enlarged prostate which he had treated. Of these 11 had required operation, nine had made good recovery, two had died, 19 cases had been treated by palliative means with more or less relief. None of these had to use a catheter, as Mr. Gunn believed that the risks of catheter life must be always greater than the risk of an operation.

Mr. **Walton Browne** (Belfast), was pleased to hear Mr. Gunn advocating not being in a hurry in dealing with such cases. He believed a good deal could be done by washing out the bladder.

Mr. C. A. K. **Ball** expressed the view that a large number of cases had been operated on in the past which, no doubt, would have lived, and perhaps in a more comfortable state, had palliative measures been tried instead of operation. He thought that palliative measures ought to be employed unless there was absolute obstruction to the flow of urine.

Mr. D. **Kennedy** thought that before recommending either palliative or radical treatment the circumstances of the patient should be taken into consideration. A well-to-do patient could afford to avail himself of skilled surgical aid, and might well decide to undergo treatment of a palliative nature; but in the case of a man without means the proper employment of a catheter or other palliative measures might be attended with difficulty.

Mr. **Blayney** considered that there was a certain amount of danger attending the return to more conservative measures in the treatment of enlarged prostate. Many cases which had ended fatally after operation would probably have recovered had radical measures been carried out earlier.

AN EARLY CASE OF LEONTIASIS OSSEA.

Mr. S. **Horace Law** read a paper on a case of the above, which will be found under heading of "Clinical Records," on page 147.

In the discussion that followed the President regarded the dacryo-cystitis, not as a coincidence but rather as the direct result of the bony growth. He thought the best mode of treatment would be extirpation of the lachrymal sac on each side, as, under existing circumstances, ulceration of the cornea of a very intractable type would be likely to occur.

Mr. **Walton Browne** alluded to the symmetrical appearance of the two eyes. If the orbits were at all involved they must, he believed, be involved to an equal extent.

HARVEIAN SOCIETY OF LONDON.

Meeting held Thursday, January 24th, 1907.

The President, Dr Sidney Phillips, in the Chair.

Clinical Evening.

Dr. **Sidney Phillips** showed a case of "Congenital Heart Disease." The patient was a boy, æt. 9. There was a loud systolic murmur over the aortic cartilage; no cyanosis. The condition was probably one of congenital narrowing of the aorta.

Mr. **Clayton Greene** showed a case of "Bilateral Cystic Disease of the Kidneys" in a man, who had come under treatment for hæmaturia. The kidneys were greatly enlarged. The question of treatment was discussed, and in view of the hopelessness of these cases the possibility of kidney grafting was raised. It was suggested that a kidney might be grafted in the scrotum, the spermatic vessels and the vas deferens being used to take the place of the renal vessels and the ureter.

Mr. **Colebrook** showed, for Mr. Maynard Smith, a case of "dislocation" of the shoulder with a fracture through the lower half of the glenoid cavity. The patient was an elderly woman, and the injury had occurred four months previously. A skiagram was shown.

Dr. **Langmead** showed, for Dr. Caley, a case of "Aneurism of the Innominate Artery," and raised the question of surgical treatment.

Dr. **Phillips** considered the case unsuitable for operation. He pointed out the difficulties in exact diagnosis, and also the general degeneration of the patient's arteries, which were unsuitable for ligature.

Mr. **Crisp English** showed a man, æt. 62, with a large tumour of the left breast. This had existed for twelve years, had greatly increased during the last twelve months, and was mainly cystic. In its upper part was a small, very hard, and nodular area.

Mr. **Jaffrey** thought that the hard portion might prove to be sarcomatous.

Dr. **Spilsbury** considered that the tumour was probably an innocent cystic growth.

Mr. F. **Jaffrey** showed a woman with a fracture of the lower end of the radius and wasting of the muscles of the hand. In spite of continued massage, the condition had improved but slowly, and it was questioned whether any nerves had been injured.

Dr. **Sidney Phillips** thought that there was no actual paralysis, and that the muscles would ultimately recover.

Dr. **Sidney Phillips** showed a man suffering from general paralysis of the insane, with atypical symptoms.

Dr. **John Broadbent** showed a case of paralysis of the third cranial nerve of rapid onset in a woman, æt. 30. Improvement was occurring under treatment with potassium iodide. It was pointed out that some of these cases of nerve paralysis ultimately developed locomotor ataxia.

CORRESPONDENCE

FROM OUR SPECIAL CORRESPONDENTS ABROAD.

FRANCE.

Paris, Feb. 3rd, 1907.

Tuberculous Laryngitis.

Tuberculous laryngitis is one of the most difficult affections to treat. The patients suffer and are impatient. The majority of medicinal agents give but temporary relief. However, besides the general tonic treatment of consumption, the laryngitis claims special remedies.

Two symptoms in particular distress the patients, dysphagia and hoarseness. For the latter, hot compresses on the front of the neck, changed frequently during the day, and cotton wool put on at night, together with hot drinks, will give some relief. The following mixture can be prescribed also :—

Dionine, 11 gr.
Tincture of aconite, 50 mm.
Cherry laurel water, 1 oz.
Canada balsam, 10 oz

A tablespoonful morning and evening in an infusion of eucalyptus leaves.

Pulverisations will act both on the hoarseness and the dysphagia :—

Menthol, 1 dr.
Proof spirit, 4 dr.
Water, 6 dr.

A tablespoonful in a glass of water for spraying the throat.

Or,

Hydrochl. of cocain, 15 gr.
Phenic acid, ½ dr.
Cherry laurel water, 1 oz.
Glycerine, 1 oz.
Water, 7 oz.

A tablespoonful in a glass of water.

For dysphagia itself the following application a short time before meals is beneficial :—

Phenic acid, 5 drm.
Cocain, 1 gr.
Glycerine, 2 oz.
Cherry laurel water, 2 oz.

Aspirations of certain powders is recommended by M. Leduc, for which he has invented a special glass tube. The powders he uses are composed of—

Iodoform, 2 dr.
Cocain, 2 gr.
Morphia, 1 gr.

Treatment of Chronic Diarrhœa.

Every practitioner has been consulted from time to time for obstinate diarrhœa, but which does not appear to compromise the general health. The patients suffer only from their diarrhœa; the alvine evacuations are often preceded by colic with abundant flatulency.

Examination of the abdomen or the different organs presents no important sign. Such a diarrhœa has neither a tuberculous nor a uræmic origin, nor is it due to ulcerations of the intestines. It seems rather to depend on insufficiency of gastric digestion. The stomach empties itself too quickly. M. Soupault, who read a paper on the subject before the Société Therapeutique, advises hydrochloric acid at the beginning of each meal, from 10 to 20 drops in a glass of sugared water.

Improvement is observed in from two to eight days, and finally a complete cure, and frequently without any change in the diet. However, M. Soupault prescribes a strict regimen, as well as enemas and antiseptic powders after meals. He treated thus 38 patients, of whom 21 were completely cured. The indications of the acid treatment are : Furred tongue gastric fermentation, and intolerance for milk diet.

The counter-indications are : Brilliant red tongue, the stomach painful to pressure, with a burning sensation, and when ulcer is suspected.

In such cases, astringents take the place of the acid treatment. At each repast a cup of infusion of wild strawberry root (20 gr. for each cup) and bismuth or ratanhia. M. Sinossier draws attention to a form of diarrhœa accompanying biliary lithiasis. It is produced exclusively at mealtimes. The patient sits down to table, feeling quite well. He has not gone far in his dinner before he experiences pain in the region of the gall-bladder, followed by an imperious desire of evacuation. He quits the table and passes a liquid biliary stool, after which he feels better.

It would be entirely wrong to treat this form by the classical means. Astringent and absorbent drugs are hurtful. A season at Vichy will give good results, or, if not possible, a drachm or two of sulphate of soda in a glass of Vichy water (warm) before each meal, and opium might be given from time to time.

M. Mathieu confirms the results obtained by M. Soupault. Hydrochloric acid succeeded with him, not only in chronic diarrhœa of neuro-arthritic patients but also in that of cancer and phthisis. He also prescribes :

Salicylate of bismuth, 6 gr.
Benzo-naphthol, 6 gr.
Resorcin, 10 gr.

For one wafer. To be taken before each meal.

Alopecia in Women.

Nothing distresses a woman more than to lose her hair, and it is the duty of the practitioner to be prepared to relieve her distress. If he succeeds in making the hair grow for his patient, she will be for ever grateful to him.

Alopecia in women might be put under two types —that accompanied by pityriasis, and that where no pityriasis is apparent. In any case, the treatment is simple, and consists mainly in stimulating lotions applied with a hard brush.

Dr. Sabourand recommends the following formulæ, which might alternate in their application, as variety in the remedies increases their actions :—

Hoffman's anodyne, 6 oz.
Spirits of camphor, 1 oz.
Spirits of lavender, 1 oz.
Nitrate of potash, 10 gr.
Formal, 15 mm.
Distilled water, 2 oz.

Acetone, 3 oz.
Proof spirit, 3 oz.
Liq. ammonia, 1 dr.
Caffein, 10 gr.
Tincture of capsicum, 4 dr.
Ess. of violets, 1 oz.
Water, 2 oz.

Hydrochlorate of pilocarpine, 10 gr.
Proof spirit, 6 oz.
Ether, 1 oz.
Spirit of lavender, 1 oz.
Rose water, 2 oz.

At the end of two or three months, new hair appears and continues to grow regularly. At the end of a year it attains three or four inches. Those patients who are not afraid of vigorous brushing are those who obtain the most satisfaction ; on the other hand, patients who fear to lose their hair by hard rubbing are certain to be disappointed as to the desired result.

Otherwise the constant success of the treatment demonstrated the difference between alopecia in women and alopecia in men. Nine times out of ten, M. Sabourand observed that in man it is a question of commencing baldness, which progresses more or less rapidly as years go by, in spite of every treatment; whilst in the same proportion in women, if the patient has not entirely recovered her hair, which is the rule, very satisfactory results are obtained.

Naturally, if some general trouble accompanies the alopecia (anæmia, hepatic colic, neurasthenia, constipation), it must be treated by the usual means. It would seem that in women, more than in men, the hair follicles are particularly sensitive to slight disorders of the organism.

GERMANY.

Berlin, Feb. 3rd, 1907.

At the Verein für Innere Medizin, Dr. Lewandowski showed a youth, æt. 15, who was suffering from

Hæmatomyelia.

He had been admitted into the Friedrichschain Hospital in August last. Before the present illness he had been perfectly healthy. He was a worker in tobacco, and had had to work in drawing the tobacco leaf out of a bag when in a bent position. Whilst at work he felt a violent pain between his shoulders, so severe that he had to give up. On dressing to go home, he suddenly collapsed and was unable to travel. The urine had to be drawn off. On admission into hospital there was complete paralysis of the right leg, less complete of the left. There was complete paralysis of the sympathetic of the right side. The second and third dorsal vertebræ were painful on pressure, but there was no spontaneous pain over them. In regard to diagnosis, it must be one of three things—(1) acute myelitis, but the sudden onset of the symptoms was against this; (2) spondylitis, but with that there would be great pain over the spine, and there was not, and an X-ray examination did not support this; (3) hæmatomyelia, hæmorrhage into the spinal column; and all the symptoms were in favour of this hypothesis. There he had now come to a standstill. The trouble was almost limited to the right side. Nothing definite could be said as to where the bleeding came from. The patient's occupation included lifting heavy bales of 80 to 90 kgm., and he had been doing this an hour before the attack. This for a youth of 15 was a good deal, and it might have caused the hæmorrhage. He would therefore have a claim to compensation for accident. In reply to a question from Dr. Cohn, he said the abdominal muscles were also paralysed.

At the Hufeland Society, Dr. Neumann spoke on a diagnostic point in connection with

Diseases of the Chest in Children.

He said that in children loud bronchial breathing was often heard between the shoulder-blades, and in front and behind on the right side an equally bronchial or prolonged expiratory sound.

This was important from a diagnostic point of view, as these symptoms had been very widely but erroneously held to be signs of phthisis. He pointed out that they were really a part of the symptoms due to enlarged bronchial glands, and he then pointed out what the other symptoms were.

At the Ophthalmological Society, Dr. Steindorff showed a patient with

Swelling of the Left Side of the Face.

It was at first taken to be a rheumatic affection, and antipyrin was given, but without effect. An examination of the adjoining cavities was then made, and both the frontal sinus and antrum were found to be dark, but no pus was found in the nose. The case was then taken to be one of mucocœle In the meantime the symptoms were getting worse; there was protrusion of the eyeball, paralysis of the oculomotor nerve, and great pain in the region of the frontal sinus, and it was decided to open the cavity. On this the striking result was obtained that there was no frontal sinus at all, that the antrum and the other sinuses were healthy. As the frontal nerve was cut through at the operation, the pain ceased, and a dull, tender spot remained. On October 10th the patient remarked that he had suddenly gone blind on that side, but the ophthalmoscope revealed nothing. Notwithstanding denial on the part of the patient that he had ever had syphilis, Hg. treatment was at once begun. Under this all the symptoms improved with the exception of the amaurosis, which showed itself to be due to gradually advancing atrophy of the optic nerve. He concluded that a periostitis that caused pressure on the nerve was the cause of the symptoms.

At the Medizinische Gesellschaft Dr. Baginsky showed a child who had become

Blind, Deaf, and Weak in Intellect through Whooping-Cough.

It had had convulsions, and the symptoms above-named had made their appearance after them. The pupillary reflex had remained, and this he took as a good omen—in fact, now there appeared to be some slight sense of sight, but the prognosis was very doubtful.

Probably the symptoms should be looked upon as of a toxic nature, but there was a possibility that they were due to multiple cerebral hæmorrhages.

The discussion on Heubner's paper on

Orthostatic Albuminuria.

was resumed by Dr. Langstein, who had made an examination of the tissue changes in Heubner's case. He found an albuminous body that could be precipitated in cold with acetic acid. No importance could be placed on increased excretion of oxalic acid. Urea and uric acid showed no changes. The disease was much more frequent than it had been thought to be. It had been found to be so especially in the polyclinics. A connection with a previous illness was very doubtful; orthostatic albuminuria had scarcely anything to do with nephritis; vasomotor disturbances probably lay at the bottom of it. Dr. Baginsky thought the affection had been considered in too "doctrinaire" a manner, and its clinical importance overestimated. He laid stress on the extraordinarily varying course, and noted its resemblance to purpura, in which, after the cessation of all hæmorrhages, they might come on again in the lower parts on the patient getting up. The kidneys as well as the vessels were probably at fault.

Hr. Fürbringer did not consider the kidneys shown sound, but did not consider the slight changes explanatory of the considerable amount of albumen passed. In his view kidney disease was not the basis of orthostatic albuminuria. He was supported in this by a case in which he gave a dietary that would have made a real kidney disease worse; he gave alcohol, large quantities of meat, meat extracts and spices, and, last of all, cold baths, and they had not the least effect on the disease.

For insurance it would not be right to reject every case of orthostatic albuminuria; the great majority of the cases, as was shown by the fact that Heubner was only now in a position to record the post-mortem condition of one.

Dr. V. Hausemann considered the cicatrices to be entirely without significance. Even fat in the kidneys was without any pathological significance so long as no cells were destroyed, and it was very frequently met with both in the human subject and in animals. He believed, however, that the cell nuclei in the glomeruli were increased for the age of the child. and from this there arose a possibility that there has been a previous glomerulonephritis.

AUSTRIA.

Vienna, Feb. 3rd, 1907.

High Tension Dyspnœa.

At the Gesellschaft, Pal communicated his experiments on paroxysmal dyspnœa produced by tension in the vessels. He divided these into two forms—cardiac asthma, which was identical with the second form, cerebral asthma—both of which could be relieved by reducing the blood pressure in the arteries. In both cases the asthma disappeared, while the cerebral symptoms were greatly improved in that form.

He further elaborated the connection between cardial asthma and angina pectoris, which, he contended, was due to stenocardia.

Lead Poisoning.

Pollek reported on a case of chronic lead poisoning, which he had exhibited to the members of the Gesellschaft two months ago. At that time he remarked that the symptoms were severe for such a short time since the onset of the injurious effect of the metal, which was estimated at three years. Since then the patient had died from lead intoxication, which was far below the usual time of exposure, recognised in these cases as thirteen and fourteen years.

Serum Diagnosis of Carcinoma.

Salomon presented a report of his investigations and experiments on the reputed ferments of cancer. His efforts were directed towards discovery whether carcinomatous tissue when injected into the body of an animal possessed any particular property on the serum of the blood. It was taken for granted that carcinomatous serum had an anti-ferment which prevented the autolysis of carcinomatous tissue. The inhibition of hæmolysis by carcinomatous serum is no more than what takes place in those cases where normal serum is used, as both are powerful inhibitors of hæmolysis. He found in one guinea-pig that when the carcinomatous substance was dried and rubbed into fine powder with common salt, and again dissolved, the solution formed a serum void of carcinomatous results. This reaction appeared in several other cases, but he would not as yet give it as a general rule, as the experiments were not sufficient to justify a final judgment.

Ranzi said that he had undertaken several experiments with serum in order to diagnose carcinoma, but his results were woefully disappointing. Neither the "precipitin," nor the "complemental deviation" methods were successful in the diagnosis. Hofbauer thought these experimental results had cleared up a point that seemed at one time very obscure, viz., carcinomatous asthma.

The etiology of the difficulty in breathing has hitherto been dissociated with serum, but recent experiments show that it is similar to the diseased thyroid which is connected with the serum elaboration that affects the breathing. Pibram informed the members that the sero-therapeutic Institute of Vienna had been working for some time with the various sera to discover a series of similarities in normal and pathological sera, but, unfortunately, up to the present time their efforts have been in vain. No classifications can be established. Klein thought that the best methods yet devised for the elucidation of this subject was the complemental deviation which fully explained the Gengou-Moresch phenomenon. Kraus remarked that Gengou, in 1902, showed that the presence of antidotes and their antigenes checked hæmolysis, but, strange to say, that Moresch three years later, without any knowledge of Gengou's results, rediscovered the same phenomenon, which gives importance to this anti-complemental system.

HUNGARY.

Budapest, Feb. 3, 1907.

At the recent meeting of the Interhospital Association, Dr. Förök read a paper on

The Treatment of Acne.

He maintained that acne is even commoner than eczema, and that while it is true that the disease is often stubborn, the majority of cases can be greatly benefited in a short time, and very many of them cured promptly. The indications for treatment are as follows:—(1) Improve the condition of the skin, so that it will no longer be a suitable culture ground for the bacillus. (2) Empty the follicles of the skin of the colonies of bacilli. (3) Keep the skin constantly aseptic, so that any bacilli that escape on it will be killed, and no new infection of the skin will be possible. The first indication is met by attention to the patient's general health, by means of baths, exercise, diet, attention to hygiene, and lastly, drugs. The follicles are emptied by the use of the curette, the acne lances, and the comedo-expresser. The best local application is sulphur, preferably in the form of the old lac sulphuris, which is mixed with carbonate of potash. Resorcin is also useful, as well as sulphur soap. The use of the X-rays should be limited to intractable cases, and requires great caution to prevent injury.

Treatment of Night Sweats.

Dr. Tauszk, writing on the above subject, says that one of the most disagreeable symptoms of early pulmonary tuberculosis is nocturnal perspiration, since it robs the patients of sleep and weakens them considerably. The cause of these night sweats is not known, but they are probably a result of the action of the toxins of the tubercle bacillus on the central nervous system. According to him, the treatment is very unsatisfactory, and hence the number of drugs recommended is legion. Antipyretics and atropine have been warmly recommended, but the former very often aggravate the condition, while a tolerance is very soon established for the latter. Agaricin is very uncertain in its action, and may cause diarrhœa, and the same applies to camphoric acid and its compounds. The author has invariably seen the best results after the use of veronal in doses of 0.3 grammes, rarely increased to 0.6 grammes. In conjunction with this, the patient should sleep in a cool room with open window, and use one of the many dusting powders recommended.

At the last meeting of the Medical Society, Dr. Levai referred to the

Therapeutical Value of Nitroglycerin.

He has tested the effect of this drug on arterial pressure in patients by means of the sphygmomanometer, and also in animals, and finds that high arterial pressure in man is not perceptibly affected by it, nor is dilatation of the blood-vessels apparent. Some of the conclusions reached are as follows:—The usual dose of nitroglycerin of 0.005 (half a milligramme) is too small to produce an effect in pathological conditions; one milligramme is a minimum dose. It is a perfectly safe drug to use. Even in large and repeated doses the speaker has never seen any ill effects. Its effects are very transient, as shown by the experiments on the dogs, and the ordinary dose of half milligram every four hours could not possibly have any effect on the arteries. Nitroglycerin is said to increase the quantity of urine (first observed by H. P. Loomis, of New York) in chronic Bright's disease; but after keeping accurate records of the daily amount of urine passed, the speaker was never able to satisfy himself that any increase seen was due to this drug. In conditions due to arterial spasms, so-called, such as angina pectoris, migraine, asthma, nitroglycerin may be of benefit, in full doses often repeated, but not in arterial sclerosis, where the arteries themselves are more or less changed.

FROM OUR SPECIAL CORRESPONDENTS AT HOME.

SCOTLAND.

Cerebro-spinal Meningitis.—During the past few weeks there has been a considerable incidence of cerebro-spinal meningitis in Glasgow, and the latest reports show that the cases are numerous enough at present to warrant the term epidemic. Up to the first of February the total number of deaths from the disease is given at 52. On the same date there were 50 cases, as compared with 35 on the corresponding day of the preceding week. Dr. Wright, chief assistant to the medical officer of health, states that 113 cases have been notified during the month; 6 of which, however, proved to be some other disease. In a large proportion of cases the disease has been very acute, death taking place in from 24 to 48 hours. Fifty per cent. of the cases have been children under 5, and 30 per cent. between the ages of 5 and 10. In Leith also several cases have occurred, and the medical officer for health has issued a circular to the pactitioners in the burgh requesting them to report any suspicious cases. It is officially stated by Sir Henry Littlejohn that no cases have occurred in Edinburgh. Special accommodation has, however, been prepared in the fever hospital for the reception of any cases that may crop up.

EDINBURGH SCHOOL BOARD MEDICAL OFFICER.—The following form the short list from which the medical officer will be chosen :—R. C. V. Ash, M.B., D.P.H., medical officer to the Carnegie Dunfermline Institution ; Katherine S. Clark, M.B., D.P.H., resident medical officer Claigleith Poorhouse ; J. D. McCrindle, M.B., D.P.H., assistant medical officer of health, Birmingham ; J. H. Merkle, M.D., D.P.H., Bacteriologist, Edinburgh City Hospital ; Robert Thornton, M.D., D.P.H., assistant lecturer on medical jurisprudence and public health, Dundee.

BANGOUR ASYLUM.—Dr. Fraser, Commissioner in Lunacy, has issued his report on the subject of Bangour village, and it was submitted to the Lunacy Board a few days since. While generally commenting favourably on the discipline and organisation of the asylum, the Commissioner draws attention to the absence of any provision for isolation or separate treatment of tuberculous patients. There are in the asylum 15 such cases, the malady being acute in 7 of them. The margin of spare accommodation for male patients is ample, but it is found that that for women may not prove enough, as, even by re adjusting the proportion of males and females in some of the buildings in favour of the latter sex, there will be, when all the presently existing cases are transferred to Bangour, only 16 vacant beds.

MORISON LECTURES ON INSANITY.—These lectures were this year delivered by Dr. Urquhart, Murray's Royal Asylum, Perth, on January 28th, 30th and February 1st, the subject selected being the prognosis of insanity. In the first lecture a retrospect of the literature of insanity was given, showing how the ancient dictum of Hippocrates, that insanity is caused by disease, had been lost sight of amid the superstitions of the middle ages, and how it had been restored by such thinkers as Van der Kolk, and established by Stras. He then referred to various researches on the pathology of insanity by ordinary clinical methods, referring in particular to Dr. Lewis Bruce's recent work on the law of insane persons. In his argument for the unity of the disease, as a result of morbid somatic conditions, he referred to Sankey's generalisation that insanity is but the process, and that the varieties are differentiated by non-essential phenomena—apart, that is, from cases of a definite pathological nature, such as general paralysis, alcoholism, epilepsy etc. In discussing the hereditary nature of the neuropathic diathesis, Dr. Urquhart adhered to Dr. Macpherson's opinion that it was a natural variation which tended to occur, just as any other variation did ; it seemed, therefore, that any rough-and-ready nostrum for eliminating the unfit was not likely to succeed. He appealed for collective evidence as to the heredity of families taken at random, until sufficient data were obtained to yield reliable results when treated by statistical and biometric methods. Proceeding (in the second lecture) to distinguish between insanity due to gross pathological changes and those whose nature was obscure, he set aside cases due to syphilis, epilepsy, alcoholism and congenital defect. In ordinary insanity of obscure cause, which he classified as melancholia, mania, and delusional insanity, he showed that mental stress was inoperative as a cause except in connection with a neuropathic heredity ; further, that the hereditary cases recover in fair proportion, though more subject to relapse than the acquired. In a study of environment it was found that middle-class patients, drawn from rural and urban surroundings, had a practically similar heredity. Town life, therefore, had no markedly evil effects, but the kind of insanity was more severe in patients from urban than in those from rural districts. In the final lecture of the series Dr. Urquhart discussed the relation of psychology to medicine, and alluded particularly to Kraepelin's work on fatigue and the revolution it had caused in the educational methods in Germany. Insanity could not be communicated from one person to another without pre existent bodily disorder, nor could hypnotism cause insanity unless the patient were neuropathic. The lecture concluded with a reference to the importance of individualised treatment, and of clinical investigation in all departments, for all have an immediate bearing on the problem of insanity.

BELFAST.

CEREBRO-SPINAL MENINGITIS.—The epidemic of cerebro-spinal meningitis has increased considerably during the past week. Up to Friday, February 1st, there had been 45 cases reported, and 20 deaths. About 20 cases are under treatment at Purdysburn Fever Hospital.

THE IRISH UNIVERSITY QUESTION.—Where professional men have met during the past week, the one topic of conversation has been the proposed legislation on University affairs, as foreshadowed by Mr. Bryce. On a subject on which opinions differ so greatly, it is hard to generalise, but among local medical men, the vast majority of whom are graduates of the Queen's or Royal Universities, the commonest feeling seems to be one of sympathy with the Trinity graduates in their strong objection to seeing their old University destroyed, as all agree it would be under the proposed scheme. As regards the local conditions, no one cares to express a definite opinion till the details of the scheme are published ; but if the changes proposed are to be made, the more autonomy they give to Queen's College, Belfast, the better most men will be pleased. A certain amount of distrust is caused by Mr. Bryce's rather cryptic remarks on University teaching in higher subjects and college teaching in lower. If he means that Belfast students are to be sent to Dublin to finish their education, the plan will be most strongly resented. As regards the probability of the scheme being passed by Parliament, it is felt that it would hardly have been made public unless the Government had obtained the agreement of the Roman Catholic authorities and the Irish National party to its principles, and also that Mr. Birrell would not take charge of it unless he were assured it was sure to meet with a kinder fate than befell his last educational effort. On the other hand, it is thought by many that the Government may not have realised the intense feeling that will be stirred up on behalf of Trinity, in which so many educated Englishmen will share ; a feeling in opposition to the proposed changes far stronger than any that is likely to be evoked in its favour, for at best it can only be looked on as a compromise. In short, if the scheme becomes law, the Act will be a congenitally deformed infant, which its parents alone love, and even they cannot be proud of.

FORSTER GREEN HOSPITAL.—The annual meeting of this hospital was held on the 31st ult., the Lord Mayor, the Earl of Shaftesbury, presiding. The medical report was read by Dr. Howard Sinclair. It stated that 1,477 patients attended the extern department during the year, and 164 were treated in hospital, the average number of beds occupied being 35. The medical staff continues to impress on the committee and on the public the desirability of treating early cases in hospital. The natural tendency of the uninformed layman is still to send to hospital the most advanced and hopeless cases.

BELFAST HOSPITAL FOR SICK CHILDREN.—The annual meeting of this hospital was also held on the 31st ult., and was presided over by Sir William Crawford. Dr. McCaw read the medical report, which showed that 837 cases had been treated in the wards, and 330 operations performed. In the extern department, 5,551 cases were treated, and the total attendances were 16,667.

LETTERS TO THE EDITOR.

INFECTIVE BRONCHITIS AND ITS RELATION TO CONSUMPTION

To the Editor of The Medical Press and Circular.

Sir,—I read with great interest Dr. Prosser White's paper in The Medical Press and Circular this week, and I find much in it which the experience of the humble general practitioner, who lives far from the madding laboratory, and who uses his own experience and common-sense as his chief guides, can confirm. But is not the chief cause of all our bronchial and nasal troubles a combination of external and internal conditions? And is infection—that is, direct infection—always necessary? It seems to me that we ordinarily and constantly carry about in our nasal and bronchial mucous membranes the germs of many diseases, but that the "chill"—the lowering of vital energy by external cause—is the effective condition That is to say, that if we sit in a draught, or get our feet wet, or sleep in a damp bed, the vitality is lowered, and the most vigorous microbe in the nose or bronchus get his chance to infect us—and frequently does so. If this is very bad nonsense, please destroy.

Yours truly,

Bacillarius.

Leicester, February 1st, 1907.

THE SCIENCE OF THE TEMPERANCE QUESTION.

To the Editor of The Medical Press and Circular.

Sir,—The views entertained and expressed by Mr. Haldane on the value of science in almost every kind of work are likely to have great influence, and it would be well if the temperance question could be carefully considered from a strictly scientific point of view.

The question is this: What is alcohol, and how is it produced? That is the first question. What is the value of alcohol in health or disease? is another question. Alcohol is the product of fermentation, a process of a very singular character. There is one thing quite certain, and that is, we may use ordinary fermented liquids without injury to digestion or health if not used in excess; but if we separate the alcohol and use that, it is a very different matter. When we have to consider how to legislate on this temperance question, we must draw the line strongly and markedly between a fermented liquid and alcohol. There would be no difficulty in working on this simple basis, and there is no doubt but that the assistance of the medical profession in settling this matter would be great.

I am, Sir, yours truly,

Temperance.

DIRTY AND INSANITARY RAILWAY CARRIAGES.

To the Editor of The Medical Press and Circular.

Sir,—The time has long passed when the better cleansing of railway carriages should have taken place. If anyone only watches the *modus operandi* at any of our stations, you cannot but be struck at the perfunctory manner in which the work is done. With a brush and dustpan the porter simply walks in one side, flings the brush about, and walks out of the other side; does not even remove the loose dust, leave alone what is trodden into the wooden floor. Soap and water is an unknown quantity with the carriages from their birth to the scrap-yard. What should be done is the removal of the seat cushions at the end of each journey, and well brushed, if the material will not allow of it being washed with some disinfecting fluid. The back cushions should be made to be removed also, and treated in like manner. The woodwork of the seats should then be washed with soap and water; also the floor, doors, racks, roofs, and sides. The seats, if made to turn up on hinges, would greatly facilitate the process of proper cleaning. But it will never be done while the work is left to such a class of men as railway porters, or carriage cleaners, as they are incorrectly called. Each railway company should have a properly qualified medical officer of health, whose duty it should be to travel up and down the line and see that the station waiting-rooms, lavatories, and all places connected with the company are kept clean and sanitary. At present some of the provincial stations are a disgrace to the company and country in which we live. How often does one see the hose turned on the platforms of a station which are in use for about eighteen hours a day, people spitting and animals running about, live stock deposited on the station to await removal, milk cans left for hours sometimes, and other articles for food consumption? The dirt and offensive matter is allowed to dry in at night. The porter runs a long brush over it, and that is sufficient until the next morning. I have known and traced infectious diseases to railway stations and carriages, but, of course, it is impossible to say which compartment or train very often. Those who cater for the public, whether carriers, or food producers or sellers, are not sufficiently under control.

Yours truly,

Edward Carnell, D.P.H

OBITUARY.

SIR MICHAEL FOSTER, K.C.B., M.A., M.D., D.Sc., D.C.L., LL.D., F.R.S.

We regret to announce the death of Sir Michael Foster, which occurred suddenly on January 29th. Born in 1836, at Huntingdon, Michael Foster was educated at University College School, and at University College, London. After taking his degree of M.B. at London in 1859, he practised for a few years as a surgeon at Huntingdon; but in 1867 he became Teacher, and two years later Professor, of Practical Physiology at University College, London. In 1869 also he was appointed to the Fullerian Professorship of Physiology at the Royal Institution in succession to Huxley. In 1870 Foster went to Cambridge to teach physiology as Prælector of Physiology at Trinity College. In 1883, by the new statutes, Cambridge was able to confer a degree upon him, and to recognise the success which had attended his efforts by endowing a chair of physiology for him to fill. He took by far the larger share in the development of the Cambridge Biological School, and his influence was not confined to the department of physiology alone. In 1900 the duties of his chair were entrusted to a deputy, and in 1903 he handed in his resignation. In 1872 Foster was elected into the Royal Society, and in 1881 he succeeded Huxley as one of its secretaries. He held this post till 1903, taking a very active part in the work of the Society, and he also found time to serve on the Royal Commission on Sewage Disposal and to act as chairman of that on tuberculosis. In 1900, when Sir John Lubbock was raised to a peerage, he was elected in his place as member of Parliament for the University of London. At first he was a Liberal Unionist, but later his opinions changed and he sat on the Liberal benches. Sir Michael Foster's own contributions to the work of original research were not very numerous, but as a teacher he exercised a profound influence. Sir Michael Foster was the author of a "Text-Book of Physiology," which was first published in 1876, and has gone through seven editions. In addition he wrote a life of Claude Bernard, "Elements of Physiology," in conjunction with Dr. J. N. Langley, and "Elements of Embryology" with F. M. Balfour; and with Dr. Ray Lankester he was joint editor of the "Scientific Memoirs of T. H. Huxley." The "Journal of Physiology" was founded and edited by him. He was created K.C.B. in 1899, and acted as President of the British Association at its Dover meeting in the same year. Many other scientific and academic distinctions also fell to his lot, including honorary degrees from Oxford, Dublin, Glasgow, St. Andrews, and the McGill University, together with membership of various foreign learned societies. He was twice married, first to Georgina, daughter of Mr. C. Edmunds, and secondly to Margaret Sarah, daughter of Mr. G. Rust.

WILLIAM M. PREES, M.R.C.S.ENG., L.R.C.P.ED.

WE regret to announce the death of Mr. W. M. Prees, of Liverpool, which occurred suddenly at the West Derby Union Offices on January 22nd. Mr. Prees had been officially connected with the West Derby Guardians for nearly thirty years, his first position in the service of the Union being that of medical officer at Mill Road Infirmary, which was then used as an infectious hospital. He held his present appointment for many years, and by all the officials in the union and amongst the poor he was held in the highest respect and esteem, and his sudden death will be deeply regretted by all who knew him. When he first came to Liverpool he started as an assistant to Dr. Sheldon, in Boundary Street, whom he left to take up the position of medical superintendent at Mill Road.

SAMUEL PARTRIDGE, M.R.C.S., L.S.A.

WE are sorry to have to record the death of Mr. Samuel Partridge, of Great Barr, formerly of Darlaston. The deceased gentleman was the first medical officer of health for Darlaston, and continued in that position for forty years. He was also district medical officer, and for 35 years was certifying surgeon under the Factory Act for Wednesbury and Darlaston. He married the younger daughter of Dr. Henry Garman, of London, sister of Dr. William Garman, of Lapley Hall, near Stafford, and leaves three sons, one of whom, Dr. Sydney Partridge, is the present medical officer of health for Darlaston.

JAMES LITTLE, M.D.ED., M.R.C.S.

WE regret to record the death of Dr. James Little, which occurred at his residence, Fleming Square, Maryport, on January 29th. The deceased, who suffered from phthisis, was in the Threlkeld Sanatorium on the slope of Blencathra for a time, and derived considerable benefit from the treatment. On getting back to work again he speedily relapsed, and in the end died from pleurisy. He qualified as M.R.C.S. (England) in 1874, and took the M.D. at Edinburgh in 1877. He was appointed a Justice of the Peace for Cumberland in 1900, was formerly surgeon-major of the 1st C.R.G.V.A., a Fellow of the Royal Institute of Public Health, and medical officer of health for Maryport. Dr. Little was a man of many parts—a successful physician, a skilful vocalist and musician, an entertaining conversationalist; in his youth he was a good all-round sportsman.

SPECIAL ARTICLE.

ROYAL COMMISSION ON TRINITY COLLEGE, DUBLIN, AND THE UNIVERSITY OF DUBLIN.

With reference to the provision made for post-graduate study and the encouragement of research, the Commission report as follows:—

"The only special provision in the College for the endowment of post-graduate study or for the encouragement of research is afforded by the FitzGerald Memorial scholarship and medal. A fund of £1,600 was collected and invested, a part being allocated to an endowment of a scholarship for the encouragement of research in Physical Science by students who have obtained the B.A. degree of the University, and who during the term of the scholarship are to carry on research in the Physical Laboratory of the College, and to take part in the practical instruction of students therein, and the residue to found a medal to be awarded to students for research work carried out in the Physical Laboratory of the College. We learn with much satisfaction that, as a result of a public effort, a new laboratory for the School of Experimental Physics has just been completed; that the accommodation for the School of Botany will be largely increased, and that the School of Geology and allied sciences will shortly receive some extension of room.

"We are of opinion that some more definite encouragement of post-graduate study and of research is essential to the full life of such an academic body as Trinity College, and without attempting to go into details we *recommend* that opportunity shall be given to some of the Probationary Fellows and to graduates of Dublin and other Universities under proper conditions as to residence or supervision, to pursue courses of independent research, whether in literary or scientific subjects, and that by way of further encouragement degrees shall be awarded for research in the University, following, so far as may seem desirable, the arrangements in that respect of the Universities of Oxford, Cambridge, Edinburgh, and London. If these suggestions should be adopted it will evidently be necessary to establish a special fund in aid of research, and, though external help may be necessary, we *recommend* that attention shall be given to the point when the whole financial position of the College is considered.

"We feel bound to add that, in spite of the absence of special endowment for original research, the publications made from time to time by both the elder and younger members of the College show that much admirable and original work, and some of the very highest character, owes its inspiration to the College."

The Commission report as follows with reference to the opinion they have formed of the character of the University, its work in the past, and the manner in which the Board has discharged its duties to the Institution:—"The University and College have not been unmindful of the advancement of learning and the widening of science; and the Board of the College has been enabled within the last fifty years, from funds partly of the College and partly contributed by friends of the College to make important additions to the teaching staff and to the equipment of the institution. From the statement in the Appendix it will be seen that within that period there have been established within the College twelve new professorships, and ten new lectureships, and that the following buildings have been either constructed and equipped or greatly enlarged and improved—viz., the Museum Building, the Medical School Buildings, the Laboratories for Mechanical and for Electrical Engineering and the new Buildings of the School of Experimental Physics. The foundations of a new building for the Botanical School are at present being laid. . . . We believe that Trinity College is capable of improvement, as we shall indicate in the course of this Report, and that it will in the future increase in strength and usefulness; but as it stands to-day it is a noble institution for the maintenance of sound learning not unworthy of its great traditions and of the affection and veneration with which it is regarded by its children. . . . We desire to express very strongly the high opinion which we have formed of the work done by the Board as the supreme power in the College, and of the liberality with which, during the last half century, it has striven to extend the area of instruction within its walls. But, nevertheless, we are of opinion that certain changes in the government of the University and College would increase their usefulness to the country."

The foregoing conclusions and remarks are signed by the whole body of Commissioners, and constitute the Report proper. To this Report is added a number of notes signed by different members. The first of these is signed by Sir Edward Fry, Sir Arthur Rücker, and Mr. S. H. Butcher, and details the reasons why they consider that any second College should be affiliated, not with Trinity College in Dublin University, but with the Royal University. The second note is signed by the Lord Chief Baron, Sir T. Raleigh, Professor Jackson, Dr. Douglas Hyde, and Dr. Coffey, and details the reasons why they think any new College or Colleges should be affiliated, not with the Royal University, but with Trinity College. The third note is signed by the Lord Chief Baron, Dr. Douglas Hyde, and Dr. Coffey, and gives with more detail some of the reasons which lead them to the conclusions stated in the previous note, and with which reasons presumably Professor Jackson does not agree. The fourth note is signed by the Lord Chief Baron, and refers to the relation between Trinity College and Dublin University. The fifth note is signed by Professor Jackson, and gives the reasons why he considers the present time an unsuitable one for forcing an affiliation between Trinity College and any newly constituted Colleges within the University of Dublin, although he approves the principles of such a scheme. The sixth note is signed by Dr. Douglas Hyde and Dr. Coffey, in which they state that they have no objection to two teaching Universities in Dublin, and express the belief that two such Universities will be necessary if the recommendations which they have made in the previous note are not carried into effect. The seventh note is signed by Mr. S. B. Kelleher, and states that he considers the demand for a College for Catholics in Dublin is unreasonable, and could not be conceded without "grave injury to the interest of Irish lay Catholics, and grave danger, at no distant date, to the peace of the country." The final article in the Report is a memorandum on the relation between the College and the University which has been added as additional information on this important point.

We think that all those who study the Report in its entirety will agree as to the painstaking and careful manner in which the Commission has discharged its duties.

Rapidly following the publication of the Report of the University Commission came a speech from Mr. Bryce, the departing Chief Secretary for Ireland, to a specially summoned deputation of representatives of the Presbyterian Church and of Roman Catholic laymen. In the course of a lengthy speech Mr. Bryce laid before his audience the principal point in the scheme which the Government intended to adopt. He repeated the four courses which were open, and to which we have already referred, and, like the Commission, reduced them to two, that of a College engrafted upon either the Royal University or upon Dublin University. He then proceeded to give the reasons which lead the Government to favour the latter scheme, and to unfold their proposals. These are briefly as follows:—The Government propose to create a new College in Dublin University such as is contemplated by the Majority Report of the University Commission. They propose to furnish it with adequate buildings and laboratories, and they hope that as regards the scientific aspect, use may be made of the Royal College of Science, and that its laboratories and apparatus may serve to avert the necessity of having to spend a great deal more money in crediting a complete set of things for the purposes of the new College. They propose to start the new College with a grant sufficient for buildings, and with an annual sum which will be enough to put it on a proper footing as a place for imparting education suitable to modern requirements. They will be able to draw for that purpose upon the funds of the Royal University. They propose that this new College shall be entirely free from any kind of theological tests, or any test to be imposed either upon governors, teachers, students, or upon persons who hold any emoluments. The governors of this new College ought to be appointed in the first instance by the Crown, and thereafter be appointed partly by the Crown and partly elected by the teaching staff and by the graduates—that is to say, the graduates belonging or attached to this new College. And when that system was in full operation the Crown nominees would be in a minority. The Royal University will be dissolved, and the graduates of the Royal University will be transferred to the new enlarged University of Dublin, which would give a national University for Ireland. The University of Dublin shall be enlarged to become a National University for Ireland, and to include as constituent colleges —(1) Trinity College, (2) the new College in Dublin, and (3) the Queen's Colleges in Cork and Belfast. Mr. Bryce agreed with the Commissioners in thinking that Cork and Belfast are not yet ripe to be created into separate Universities. This enlarged University of Dublin would be administered by a governing body or senate, partly nominated by the Crown and partly created by election, chosen by University teachers and by the whole body of graduates. The graduate representatives could be increased later on.

The University will be absolutely unsectarian, and there will be no tests for governors, fellows, if any, teachers, students or examiners. The University governing body will control and direct examinations, appoint University professors, subject to the approval of the Crown. The teaching in the Colleges would be supervised by the College bodies. The University would provide teaching in advanced subjects which are non-controversial subjects.

Whatever can be said for or against this projected scheme, one thing is obvious—that, apart from the question of names, the effect of Mr. Bryce's proposal is not to abolish the Royal University, and to enlarge Dublin University, but to abolish Dublin University and to add Trinity College to a reformed Royal University.

It may be well to repeat here the extract from the "Notes" appended to the Report of the University Commission by Sir Edward Fry, Sir Arthur Rücker, and Professor Butcher. Referring to the proposal to add the new College to an enlarged Dublin University, they say:—

"Trinity College rejects it. Lord Justice FitzGibbon, in refusing to accept it, speaks probably the general voice of his Protestant brethren. Mr. O'Reilly, expressing, as he believes, the opinion of the great mass of the Roman Catholic laymen of Ireland, considers it the worst of all proposals and intrinsically impracticable. The Rev. Dr. Delany, who may be taken to represent the higher Roman Catholic teachers in Dublin, reprobates it. The Rev. Dr. Hamilton, speaking for Belfast, Dr. Windle for Cork, and Dr. Anderson for Galway, are unanimous in their disapproval; and if possible still more important is the condemnation unanimously passed upon the scheme by the Senate of the Royal University at a large meeting of that body, which probably more thoroughly represents the higher education in Ireland outside Trinity College than any other body in Ireland."

On Friday last the evidence given before the Commission was published in a large Blue-book which possesses great interest for those who would understand the relation between Mr. Bryce's proposal and the opinions of those examined before the Commission. The principal medical witnesses were Dr. A. C. O'Sullivan, F.T.C.D., Professor of Pathology in the School of Physic, Trinity College; Dr. A. F. Dixon, Professor of Anatomy; Dr. W. H. Thompson, Professor of Physiology; and Dr. McWeeney, Professor of Pathology in the School of Medicine, Cecilia Street, Dublin. Two other events of importance have also occurred during the past week. On Thursday last a meeting, composed of about 50 members of the Staff of Trinity College and the College Council, was held, under the presidency of the Provost, for the purpose of further considering the Government scheme, as outlined by Mr. Bryce, for settling the Irish University question. It was unanimously resolved:—"That this meeting, consisting of the Provost, Fellows, ex-Fellows, Professors, Lecturers, and members of the Council, summoned for the purpose of considering Mr. Bryce's speech of January 25th, is unanimously of opinion that the scheme which he outlined would be fatal to the best interests of liberal University education in Ireland, as well as unjust to Trinity College." A Committee to be called the Dublin University Defence Committee was also appointed. On Friday a meeting of the Bishops of the Church of Ireland was held, at which resolutions opposing Mr. Bryce's scheme were adopted. Further, a most emphatic protest has appeared in the pages of the *Cork Examiner*, in which the scheme is described as a "deliberate insult on the country and on its most eminent and most competent spokesmen of every creed, class, and province."

REVIEWS OF BOOKS.

NUNNELEY ON ANEURYSM OF THE AORTA. (*a*)

The disease described in this monograph is, as the author remarks, one which escapes diagnosis very frequently. The symptoms are very often obscure, and, moreover, the very rarity of the disease causes it to be diagnosed with reluctance. The author takes a very modest estimate of his book, which is admirably written. The etiology of the disease is carefully considered, and in this connection it is noteworthy that in sixteen out of thirty-two cases death occurred before the age of 35. Nearly 50 per cent. of the cases are found to occur between the ages of 30 and 40. The majority of patients are women, while sudden violent effort generally produces the aneurysmal dilatation rather than continuous heavy work. Rupture of the aneurysm is by far the commonest mode of termination. The symptoms observed are pain, gastro-intestinal phenomena, cough and dyspnœa, spasm and twitching of the leg muscles, œdema of the right leg (in one case), retention of urine, and insomnia. The diagnosis is very carefully considered, and reference is made to the statement of Prof. Osler that in old men with thin abdominal walls a very sclerotic aorta may suggest aneurysm. The question of treatment is fully and fairly discussed. Reference made to the gelatin mode of treatment is to be noted, because the author considers it no more satisfactory as regards results than the Tufnell treatment. Röntgen-ray examination is only of service as a means of confirming a positive diagnosis.

The second part of the volume is taken up with records of cases, numbering thirty-two in all, and drawn from St. George's Hospital. Short histories are given as well as an account of the *post-mortem* findings in each case. These records are of great interest and permanent value to clinicians. The author supplies a table giving the more important data regarding these cases under separate headings. The volume contains a great deal of practical information, and adds not a little to our knowledge of this fortunately rare disease. The author was well advised in publishing this dissertation in book form, as it fills up a vacant corner in medical literature in a way which must at once commend itself to the profession. We cordially commend this monograph as a very valuable supplement to the ordinary text-books on medicine.

CARTER ON PRACTICAL MEDICINE. (*b*)

There are probably few medical men who do not remember using this text-book in their student days or as a work of reference in the early years of practice. We have now before us the ninth edition of this standard and well-approved manual. It has stood the test of time, and forms one of the best elementary introductions to the study of medicine that have been published. In this edition the chapters on Pathology and nervous diseases have been revised by Dr. Stanley Barnes, while the section on skin diseases has been revised by Dr. Douglas Heath, Otherwise there are but few changes to note in this edition. The nomenclature adopted is sensible. Thus pulmonary tuberculosis is used as synonymous with the older term, phthisis, and pulmonary fibrosis as equivalent to interstitial pneumonia. In speaking of the operative treatment of appendicitis, Dr. Carter mentions that this should not be undertaken hastily, and that apart from sudden perforation and general peritonitis, it is rarely justifiable earlier than the fourth day. A valuable feature of the book is the collection of typical prescriptions appended. They will serve as models for the student to follow in writing his own prescriptions in any particular case.

As a handy introduction to the study of the Practice of Medicine, Dr. Carter's book would be hard to beat. It has several rivals, but it bids fair to hold its own against all newcomers. Its teaching is sound and practical, and the student who masters its pages will have his mind stored with valuable facts which will serve him in good stead not only in his final examination, but in the actual practice of his profession. We congratulate the author on the success of his efforts to produce an introductory manual of practical medicine, unburdened by needless details and theoretical discussions.

DISEASES OF THE EAR, NOSE, AND PHARYNX. (*a*)

The authors of this text-book have designed it primarily as a treatise on diseases of the ear and their treatment; affections of the nose and pharynx are only dealt with as subsidiary though essential causes of many aural troubles. The first chapter is devoted to a description of the various special methods of conducting examinations of the ear and nose, and we note that the writers, in contradistinction to most British rhinologists, use the palatal hook for posterior rhinoscopy. Next comes an outline of the anatomy of the external ear and auditory canal, followed by an account of the diseases of those structures. We are not prepared to accept in its entirety the authors' view of the pathology of hæmatoma auris in the insane, especially the statement that when it occurs it is a symptom "which points to an incurable form of brain disease." This, perhaps, is not so astonishing as to learn (page 112) that "very small fish have been known to enter the auditory canal while the victim was bathing. . . . Cases have been seen by the authors." In face of this assertion, we do not doubt that the fish did enter the auditory canal, but we must stipulate for their being "very small"—if we are to swallow them. Next comes the anatomy of the middle ear, which is sufficiently entered upon, as is also the physiology of hearing. The rest of the book consists of a satisfactory, straightforward account of the diseases of ear and nose, and the methods by which they are best treated. In the causes of deflection of the nasal septum, it is noticeable that early adenoid hypertrophy causing malformation of the palate and nose is not given the prominence to which we ourselves think it entitled, and in the operations for rectification of deflection, submucous resection, which gives such good results over here, is not favoured by the authors. In the operation for adenoids, it is recommended that the tissue to be removed should be painted or injected with 1-1,000 solution of adrenalin chloride immediately before operation, in order to lessen hæmorrhage. This is new to us, and seems difficult to accomplish, while we can hardly admit that the danger from hæmorrhage is "considerable," at any rate within our own experience. A "distinguished surgeon of New York" is taken to task for saying that while writers on aural surgery say much about the neglect of diseases of the ear occurring in the course of the exanthemata, he has found no means of doing anything to prevent the breaking out of such disease while measles and scarlet fever are going on, and he does not know, after all the warnings, that there is anything really to be done. We not only find ourselves in agreement with this surgeon, but also confess to finding no reason in what the authors tell us for altering our opinion. The rapid and insidious advent of middle-ear implication in these maladies baffles any prophylactic measures that we are acquainted

with. The very small fish is nearly equalled by another incident related by the authors towards the end of the book, in which deafness from "affection" of the labyrinth resulted (apparently) from a kiss upon the ear. Finally, we may say we are cordially in agreement with the view that the medical treatment of deaf-mutes should go hand in hand with their education. Taken all round, this is an interesting book; it shows independent thought and opinion, and is not without a certain attractiveness of its own.

STEWART ON NERVOUS DISEASES. (a)

It is with considerable pleasure that we welcome the appearance of this volume. Such a book has long been wanted, and the present writer has judiciously supplied the demand. If we may judge from his style, he is accustomed to teach, and reflects his methods in clearness and directness of exposition, in attention to system, and in an apt discrimination between essentials and non-essentials. As he points out in his preface, it is seldom that diseases are met with in their typical forms, and hence the importance of being able to properly co-relate symptoms and physical signs in making a diagnosis. His aim is to put the student and practitioner in the position to do so as far as disease of the nervous system is concerned, and, in fact, to obviate the necessity of wading through long and often theoretical descriptions of many morbid states before coming to a definite conclusion about a doubtful case. The book commences with a short description of the clinical anatomy and physiology of the central nervous system, and in it we notice that he adopts, without comment, the view that most of the many fibres for touch, temperature and pain cross in the spinal cord soon after entering it, and proceed upwards in the contralateral region. The table on page 22, summing up the symptoms found in upper and lower motor neuroses respectively, will be found useful, but might have been supplemented by a similar state of "sensory neurosis" symptoms. The following chapter contains a very complete case-taking scheme, and then follow chapters on such symptom groups as coma, postures and gaits, tropho-neuroses, disorders of articulation, &c. It is unnecessary to criticise the facts in these, as they contain nothing that is specially new, and owe their value to the method in which they are treated. We may, however, express surprise at one point, namely, that Downs' view concerning the course of the taste fibres through the root of the fifth nerve is the one adopted, in spite of the large amount of clinical and pathological evidence which now exists against it. A chapter also is given on "reflexes," and on electro-diagnosis, both of which are admirable practical summaries of the subject dealt with. The book is profusely and well illustrated, and in particular we would draw attention to the well-selected series of photographs from clinical cases which are used to illustrate different points.

SCHOOL HYGIENE. (b)

There is no doubt a call for a book of the type before us in these days of carrying sanitary war into the elementary school, and we have not come across any short work on the subject which embodies as much information of a modern sort as does this little work by Dr. Porter. But we are not sure that, admirable as it is in many ways, it is quite the ideal text-book. To begin with, the descriptions of the structures and functions of the body seem to us to take up a disproportionate amount of space, and considering that the persons for whom the book is intended are supposed at the outset to have no anatomical or physiological knowledge, we think a lighter and more elementary style would be more helpful to them. Then, too, when teachers read a book by a medical man, they want something more than they can get from health lecturers and people of that sort, and it seems to us a matter for regret that Dr. Porter did not dwell more fully on the medical aspect of children's departures from health, especially the early and insidious manifestations. What he does say is good, sound, and sensible, and perhaps in the next edition he may see his way to expand this portion, even if he does so at the expense of the anatomical detail. But the book is one which can be safely recommended, for it is carefully and conscientiously written, and is quite straightforward and free from bias.

FOOD PRESERVATIVES. (a)

A medical man, although he may not often be brought into touch with the subject of this book from the scientific point of view, should be conversant with the broad facts of the subject. Unfortunately, this branch of science has not yet reached the stage when dogmatic assertions can be made, and in order to gain even a superficial knowledge, it is necessary to consider many experiments (often of an apparently contradictory character), and to make one's own deductions therefrom. The authors have, however, done their best to condense and elucidate the subject in its different aspects, and the reader is put to a minimum of trouble in connection with the acquirements of a knowledge of the subject.

Briefly put, the views of the authors may be stated to be that although of opinion that milk should be free from preservatives, yet other comestibles are not to be condemned on this ground, except the preservative be present in obviously injurious amounts. "It is impossible to say definitely that a single case of illness has ever been conclusively traced to the preservative," and "the old preservatives are permitted without question, although some of them are more deleterious if taken in immoderate quantities than their more modern substitutes."

There is one important point on which we find the book deficient: there are no figures given of the nature and amount of preservatives in well-known proprietary articles of food, with the exception of one or two instances mentioned under "Legal Cases."

HEATH'S MINOR SURGERY AND BANDAGING. (b)

We have before us the thirteenth edition of this well-known work. The fact that it is the thirteenth renders it unnecessary, and indeed impossible, to say much about the book. A careful examination has, however, led us to feel assured that it has been thoroughly brought up to date, and that it is fully entitled to retain the position it has held for so many years as a trustworthy guide to the house-surgeon and senior student in the performance of their duties. Owing to the death of the author, the present edition is produced under the able editorship of Mr. Bilton Pollard. Its original character, however, is maintained, and the alterations and additions, whilst only slightly increasing the size of the volume, have, if possible, enhanced its usefulness for the purposes already mentioned. We confidently expect that the reception of this new edition will be as favourable as that which has been given to the earlier ones.

WEEKLY SUMMARY OF MEDICAL LITERATURE, ENGLISH AND FOREIGN.

Specially compiled for THE MEDICAL PRESS AND CIRCULAR.

RECENT SURGICAL SUMMARY.

Ante-Partum Ophthalmia.—Stephenson and Ford (*The Ophthalmoscope*, April, 1906) analyse 31 published cases and 17 observed personally to show the occurrence of ante-partum ophthalmia. The paper is long, but the summary of conclusions shows that they prove their point. They are: (1) Instances of ante-partum ophthalmia are not so uncommon as hitherto believed. (2) About one-half of the cases (44.5 per cent.) are satisfactorily accounted for by a premature rupture of the membranes, allowing access of micro-organisms to the baby's conjunctival sac. (3) In the remaining cases (55.5 per cent.), a slight injury to the membranes may determine access of micro-organisms, or infection through the uninjured membranes must be assumed to have taken place. (4) Increased temperature of the conjunctival sac in utero, enhanced virulence of the causative micro-organisms, feebleness of the babies, slight lateral tears of the membranes, position of the fœtus in the maternal passages, and the condition of the placenta cannot be shown to be connected with the causation of ante-partum ophthalmia. (5) Several so-called congenital anomalies of the eyes, as corneal opacities, staphyloma, micro-ophthalmos, cryptophthalmos, and lacrymal abscess, are probably to be explained on the theory of an intra-uterine infection. M.

Injection of Alcohol in Facial Spasm.—Abadie and Dupuy-Dutemps (*Arch. d'Ophthal.*, February, 1906) have treated a case of one-sided facial spasm by deep injection of stovaine and alcohol into the facial nerve trunk. The operation was followed by paralysis of the facial nerve, which disappeared slowly. After two and a half months the paralysis had disappeared. The authors recommend the procedure as being free from danger, painless, and as superior to division of the nerve, which is usually followed by permanent facial paralysis M.

The Treatment of Paralytic Talipes Valgus by Tendon Transplantation.—Kilvington (*Brit. Med. Journ.*, Jan. 19th, 1907) reports three cases in which this treatment was employed satisfactorily. Case 1.—Child, æt. 4½ years, had paralysis of both tibial muscle and the extensor longus hallucis of the right leg. The flexor longus hallucis and communis digitorum were weak. Operative treatment was as follows:—The peroneus longus was cut as long as possible, brought across the front of the joint, and fixed to the inner and under surface of the scaphoid by silk sutures. About one-third of the tendo Achillis was split off its inner side, the separation extending well up into the calf muscle. The muscle thus formed was placed behind the inner malleolus in the sheath of the tibialis posticus, and fixed to the under surface of the scaphoid. The sheath was accurately stitched over the new tendon. The displaced posterior tibial tendon was fixed to the os calcis. Marked improvement in walking resulted, but subsequently it was decided to ankylose the mediotarsal joint to give greater stability to the foot. Case 2.—Child, æt. 3½. The tibials of the right leg were paralysed, and there was weakening of the inner head of the gastrocnemius, inner part of the extensor communis digitorum, and the inner hamstrings and adductors of the thigh. Treatment consisted in fixing the divided tendon of the extensor longus hallucis into the under and inner surface of the scaphoid. The peroneus longus was brought across the ankle and fixed to the peripheral end of the divided extensor longus hallucis. Case 3 is similar to No. 2. The author considers that the peroneus longus would be more efficiently employed in supporting the ankle-joint behind by passing it underneath the tendo Achillis and fixing it to the navicular bone. As regards technique, the transplanted tendons were fixed directly to bone where possible by silk sutures. A periosteal flap is previously raised, and subsequently sutured over the fixed tendon. No doubt the immediate results are better if the transposed tendons are fixed to the peripheral ends of the paralysed ones. The denervated structures, however, subsequently stretch, and the operation is nullified. S.

Intraperitoneal Implantation of the Ureters into the Colon.—Barling (*Brit. Med. Journ.*, Jan. 19th, 1907) reports the case of a young man, æt. 20, who five years ago suffered from fracture of the pelvis with rupture of the urethra and laceration of the neck of the bladder. Suprapubic drainage was then employed. In June, 1906, the whole of the urine escaped above the pubes, and there was, in addition, a suppurating sinus leading to the fractured bones. As an attempt to secure the patency of the urethra was unsuccessful, the following operation was performed, first on the left and later on the right ureter. The ureter was secured as it crosses the bifurcation of the common iliac, and lifted out of its bed for about an inch and a half. It was divided, and the lower end ligatured. An incision about one-third of an inch long was made on the inner side of the piece of colon selected. The upper end of the ureter was threaded with a fine catgut suture, the needle attached to which was passed into the opening in the colon, across the bowel, and through its opposite wall. By means of this suture the ureter was drawn inside the bowel, and held in position, while a first row of sutures fixed the outer coats of the ureter to the margins of the incision in the intestine. A second row of sutures approximated the peritoneal covering of the bowel to the outer coat of the ureter. The suture through the wall of the colon to retain the ureter while suturing fixed it, was now cut short, and its point of exit secured by a single mattress suture. The colon was displaced somewhat inwards towards the middle line, and the inner edge of the divided posterior peritoneum was sutured to the inner margin of the colon as further security against leaking. Since the operations three months ago, the patient has improved greatly, and is now able to earn his living. His bowels act almost every four hours when he is up, and at longer intervals when he is in bed. His temperature is normal, there is no complaint of pain over the kidneys, and neither kidney can be palpated. S.

Practical Points in the Operation of Colostomy.—Kelsey (*Med. Record*, Jan. 12th, 1907) points out that in cancer of the rectum, which is inoperable, no palliative measure has ever been devised approaching colostomy in its benefits, where it is done, as it always should be, early. The author considers that the average duration of life in cancer of the rectum after colostomy is much longer than after extirpation, though, of course, there is never a cure. In most unsatisfactory and fatal cases, operation has been done after there were symptoms of obstruction. In the author's experience the patients on whom he has done colostomy for any cause have been cleaner, more comfortable, and have had better control of their passages than those upon whom, after extirpation, the gut has been brought as near the natural anus as the operation allowed. The other indications for colostomy are congenital malformities of the rectum and anus, extensive ulceration, recto-vesical fistula in either sex, unless very small, and in some cases of acute intestinal obstruction. As regards technique, it is important to decide whether the opening is to be permanent or only temporary. In the former, steps must be taken to ensure absolute efficiency with the greatest amount of control, and with the certainty that nothing can pass below the opening. If the opening is temporary, efficiency must be somewhat sacrificed in order that the gut be as little injured as possible. In temporary operations sutures should be passed through the edges of the abdominal incision, the parietal peritoneum, and the walls of the gut. In the permanent operation the parietal peritoneum should not be included in the suture. In severe and long-continued cases of chronic obstruction, operate on the right side instead of the left, and make the opening temporary, with the idea subsequently of enlarging it and allowing it to remain, or preferably closing it and substituting an opening on the left, if conditions admit. The reason for this is that in such cases the greatest accumulation is often in the cæcum, that the sigmoid is likely to be so distended with solid fæces as to make a proper colostomy opening impossible until it has emptied itself, and that an opening in the sigmoid, even though large and free, may fail entirely to give relief to the distended large bowel before fatal results are caused. Any of the operations for an artificial anus may as well be completed at the time as to wait two or three days before opening the gut. Until it is opened there is generallv complete obstruction at the site of the spur, both for gas and solid matter, and the condition of the patient must be carefully watched. Often in 48 hours all the symptoms of acute obstruction may be acutely marked. Sigmoid colostomy may be impossible for three reasons. The gut may have no mesentery; it may be so implicated in cancerous disease as to be either unrecognisable or absolutely fixed and immovable, or it may be over-distended with fæces so that a lateral incision without a spur is only possible. In all these cases the abdominal incision should be closed, and an artificial anus made elsewhere. In closing an artificial anus, where the bowel has been too much injured to allow of plastic procedure, the recent experiments of Cannon and Murphy would indicate that end-to-end anastomosis is always preferable to lateral, in that the circular fibres are not cut longitudinally, and peristalsis is not therefore rendered impossible. S.

Congenital Dislocation of the Patella.—MacLennan (*Glasgow Med. Journ.*, Jan., 1907) describes the case of a girl, æt. 14 years, in whom complete dislocation of the patella outwards took place on flexion. There was slight asymmetrical genu valgum, in this patient, rather a sequence than a cause of the dislocation. There was no deformity of the condyles. Atrophy of the vastus internus was markedly present, but whether the result, or as one of the causes of the slipping of the patella was impossible to say. Operative treatment was as follows:—The tendon of the semitendinosus was isolated above the condyles of the femur, freed from its attachment from the tibia below, and drawn through the upper wound. The skin was then tunnelled through to the inner side of the patella, part of the capsule and periosteum slit, and the semitendinosus drawn through and stitched in position. The wound healed by first intention, and now (four and a half months later) the knee can be fully flexed without dislocation of the patella, the genu valgum is diminishing, and no inconvenience is experienced by the girl from the tendon transplantation. S.

The Surgery of the Large Venous Trunks.—F. Lejars calls attention (*La Tribune Med.*, Oct.) to the fact that the trunks of large veins are no longer outside the domain of surgery, as the danger of septic thrombosis may now be reduced to a minimum. Lateral suture, when practised in suitable conditions, may be applied to all large veins, including the cranial sinuses; the union of a divided vein by end-to-end amastomosis is but rarely applicable. Lateral suture is indicated when the wound in the vessel is small and well-defined; it should not be attempted when it is contused, or ragged and situated among suppurating tissues. Longitudinal tears of whatever size are suitable for suture, the results being very favourable. When the wound is transverse, suture is inadvisable if it exceeds the semi-circumference of the vein. Circular suture of large veins has not often been performed, and should never be done unless all the surrounding circumstances are favourable for the operation. The wounded vein should be emptied by digital pressure, or, if necessary, by ligature or instrumental pressure. In either case this must be very gently applied. The rent in the vein can best be closed by a continuous suture of fine silk, threaded on a round needle, and passed as a through-and-through stitch. It is useless to attempt a Lembert suture; the walls are too thin; so that a perforating suture becomes inevitable. It is well to carry the line of sutures a little beyond each end of the actual rent in the vessel. At first, when the blood is allowed to flow through the mended vein, it oozes to some extent, but pressure with a tampon will in most cases completely check this bleeding. G.

Streptococcic Appendicitis.—Emil Hain (*Zentralblatt fur Chir.*, January 12th, 1907) has studied specially that form of appendicitis due to the presence of streptococci. This form is always a severe one, at times seems to be endemic, and undoubtedly occurs at certain times of the year, during March and April, and again in autumn during October and November. It is rare to meet with a case at other times during the year. In streptococcic appendicitis the symptoms, as a rule, are severe, and are often associated with herpes or icterus. The appendicitis caused by the coli bacilli is much milder in character, and occurs with equal frequency during the entire year. The actual cause of appendicitis seems to vary in different countries; in northern lands it is associated with pneumococcus and bacillus coli. In Germany, France, and America it is more often caused by streptococci or coli bacilli; in England and Italy coli are much the commonest cause of this disease. This difference in the etiology of the disease probably accounts for the differences often seen in the statistics of the disease in various countries, the mortality being much higher in some than in others. Streptococcic appendicitis shows a predilection for young people. It is rather rare among older patients, but when it does occur in a patient who has reached adolescence, the prognosis is very bad; cases occurring among children are fairly hopeful. The prognosis of this form of appendicitis will depend more on the time at which the operation is performed than on anything else; the earlier the organ is removed the better the patient's chances. The so-called "intermediate" stage cannot, as a rule, be recognised in these cases. As a general rule, unless the appendix is removed within three days from the commencement of the attack, the patient will hardly recover. G.

Errors in the Treatment of Cutaneous Cancers.—A. R. Robinson (*New York Med. Journ.*, Dec. 29th, 1906), in a paper on this subject, sums up his experience of 24 years as follows:—(1) Every case of cutaneous cancer demands special consideration, special study, and special selective treatment. (2) No one method of treatment of cancer is best or most efficient for all cases of operable carcinoma. (3) All cases of multiple cutaneous cancer, and all aged persons with cutaneous cancer, require internal treatment in the form of diet and drugs, in addition to local measures. A diet of milk and green vegetables, and the avoidance of meats in general, and of meats of such organs as liver and kidneys in particular, and the avoidance of alcohols, is advisable in all cancers, whether the disease be external or internal. Thyroid extract should be given in as large doses as can be borne by the patient in all cases where there is a senile condition of the skin, and in most superficial epitheliomata. (4) A knowledge of the kind of cancer present, the pathological anatomy, and the manner of extension of the disease in general, and of the special variety of the case to be treated, is necessary to a correct choice of method of treatment. (5) When possible, all cases should be under observation at least one year after commencing treatment of any kind in order to treat promptly any recurrence of the disease. (6) Early diagnosis and correct treatment place cutaneous cancers among that class of diseases which do not deserve the name of "incurable" diseases, as, almost without exception, they can be successfully treated if the method employed be the correct one. G.

MEDICAL NEWS IN BRIEF.

Dispute as to Site for a Consumptive Sanatorium.

An enquiry has just been concluded before a Local Government Board Inspector as to the safety or otherwise of placing a sanatorium for consumptives on the banks of a small tributary of the River Lee some sixteen miles above the City of Cork. The proposed site is known as Myshall, and is situated on the Tullig River. A newspaper correspondence having started as to the probability of contamination of the Lee, which provides the drinking water for Cork, the Corporation became alarmed and asked for an enquiry. The proceedings extended over four days. Dr. C. Theodore Williams, of London, gave evidence expressing general approval of the site. Mr. Fairley, engineer, of London, said that the effluent might be safely discharged into the Tullig River. Professor McWeeney, in his evidence, stated there was no danger to be apprehended from the sewage. In the course of cross-examination he stated that tubercle bacilli can live in river water, but not for an unlimited time, and that it would be highly dangerous to drink a tumbler of water into which a consumptive patient had expectorated. Dr. A. E. Moore, lecturer on bacteriology at the Queen's College, Cork, said he disapproved of the effluent being conveyed into the river, and pointed out how the arrangements for purifying the sewage might break down, with the result that intestinal tubercle bacilli could find their way into the river. He considered the fact of the patients expectorating into the river would be a distinct source of danger. Dr. A. R. Parsons, of Dublin, visiting physician to the Newscastle Sanatorium, and Mr. F. K. Etlinger, superintendent of Cotswold Sanatorium, considered the site unsuitable for a sanatorium. Among other witnesses examined were three Cork medical men and two of the Cork engineers. It is believed that if the decision of the Local Government Board should be in favour of the Myshall site, the Cork corporation will appeal to a higher tribunal.

Concert in Aid of Sir Patrick Dun's Hospital, Dublin.

A concert in aid of Sir Patrick Dun's Hospital, under the patronage of their Excellencies the Lord Lieutenant, K.T., and the Countess of Aberdeen, and the Right Hon. the Lord Chancellor and Lady Walker, will be given in the Examination Hall, Trinity College (by kind permission of the Provost and Fellows), Thursday afternoon, February 7th, at 3.30 p.m. The concert is being organised by Madame Coslette Heller, who took her "Irish Ladies' Choir" to America last year, and had a most successful tour. The vocal items on the programme will be supplied by members of the choir. Miss Madge Murphy is a particularly gifted violinist, and Miss Macdonald, the harpist, is a professor at the Guildhall School of Music, London. Mme. Power O'Donoghue is to recite. Mr. Twelvetrees is very generously also giving his services, and his name alone ought to ensure the concert being a success.

Prestwich Workhouse Case.

The following letter has been published by Dr. H. W. Boddy:—

Dear Sir,—In the report sent to you from the Local Government Board of the inquiry lately held about the lunatic, W. W. Cowan, there are criticisms of my conduct in these affairs, and I should be glad of your permission to defend myself, as far as I can, against these adverse statements, and will take them in the order of the report.

First of all, I visited Cowan in little more than an hour after hearing of his admission, so there was not much delay on my part.

Secondly, that as I am not a resident medical officer, I could not give personal supervision to a great extent to the bathing and feeding of lunatics. I have usually been consulted by the attendant as to placing patients in the padded rooms, and have ordered their removal from such rooms when fit for it. If Cowan was in the padded room for hours before I knew of it, no one ought to hold me responsible. I have only two books that relate to lunatics. The first entry in the examination book might not be accurate, as the light in the padded room at night is a very poor one, and I could not see the patient at all well. The second entry was a perfectly accurate one as far as I could make it. In the Restraint Book I stated that he was in the padded room eighty-two hours, a perfectly accurate statement, and all that was required. And yet the Inspectors say that these books were almost useless as records.

Thirdly, in the Pauper Lunatic Examination Book, as the result of examination on discharge of the man Cowan from the workhouse on July 26th, I had made an entry, "Fracture of rib (doubtful)," this being an addition made next day. The facts were these: While examining him for a moment I thought there might be a fractured rib, but did not find it on further examination, so I did not think it wise to enter a doubtful fact into the book and cause perhaps unnecessary trouble. On the next day, on receiving from the asylum the report of Dr. Clowes that Cowan had a "fractured rib or ribs," I thought myself justified in making this additional entry in the book. for I was reminded of the doubt that I had in my own mind for a short while at the time of examination, and as I could not then make a second examination of the man, I did not think it necessary to enter a second date.

All these facts were fully and quite voluntarily stated by me (without any questions being asked) on the morning of October 30th at the inquiry then being held, so the words "elicited from the medical officer" give quite an unfair idea of what took place. Had I not told them myself that "fractured rib (doubtful)" was an addition made next day, the inspectors might never have know of it at all, and, moreover, I made the statement before any questions were asked, as could be proved by the written reports of the inspectors and by the report of my solicitor, Mr. Humphreys. I do not think, therefore, that I at all deserve that the epithet "most reprehensible" should be applied to my very straightforward conduct, since I made no attempt to conceal any of this matter. I will only add that I, as well as others, have been treated very harshly and severely by the inspectors of the Local Government Board, no account having even been taken of my twenty-six years of honourable service at the Prestwich Union.—I remain, dear Sir, yours faithfully, H. W. BODDY, M.D.

Medical Sickness and Accident Society.

The usual monthly meeting of the Executive Committee of the Medical Sickness, Annuity, and Life Assurance Society was held on the 25th ult. As is usual at their first meeting of the year, the Committee considered special reports on the condition of all those members who are considered to be permanently incapacitated. Thirty-five of such reports were submitted, and few gave any hope that the member would ever be able to resume professional work. The sickness pay allowed is usually one hundred and four guineas a year, and the annual disbursement of the society in respect of these chronic claims now amounts to about three thousand pounds. The records for 1906 show that the Society has saved a considerable portion of its income, and made a substantial addition to its already large reserves. Prospectuses and all further particulars on application to Mr. F. Addiscott, Secretary, Medical Sickness and Accident Society, 33, Chancery Lane, London.

Army Medical Corps.

Consequent on the amendment of the Royal Warrant for Pay in regard to the promotion of Officers of the Royal Army Medical Corps, the Surgeon-Generals and Colonels on the Active List will be shown as removed from the Army Medical Staff and Royal Army Medical Corps respectively, retaining the ranks of Surgeon-General (ranking as Major-General) and Colonel (substantive rank in Army) respectively.

PASS LIST.

Royal College of Physicians of London.

Diplomas in Public Health were granted by the Royal College of Physicians, conjointly with the Royal College of Surgeons, on January 31st to the following candidates:—

Alexander Gray Banks, M.D., Ch.B. Glasgow, Glasgow University and King's College; Harold Graves Bennetts, M.B., C.M. Sydney, Sydney University and King's College; Woodley Daniel Betenson, L.R.C.P., M.R.C.S., St. Bartholomew's Hospital; Breadalbane Blacklock, M.B., Ch.B. Edinburgh, Edinburgh University and St. George's Hospital.

Robert Bruce Ferguson, M.D., B.C. Cantab., L.R.C.P., M.R.C.S. Cambridge University, St. Mary's and University College Hospitals.

James Henry Hugo, D.S.O., captain I.M.S., M.B., B.S. London, L.R.C.P., M.R.C.S., St. Bartholomew's and University College Hospitals.

Sydney Price James, captain I.M.S., M.D. London, L.R.C.P., M.R.C.S., St. Mary's and University College Hospitals.

Alfred Ernest Conquer Keble, major R.A.M.C., L.R.C.P. and S.I., Dublin University and Royal Army Medical College.

Percy John Probyn, D.S.O., captain R.A.M.C., M.B., B.S. London. L.R.C.P., M.R.C.S., Charing Cross Hospital and Royal Army Medical College.

Oliver Long Robinson, major R.A.M.C., L.R.C.P., M.R.C.S., Dublin University and Royal Army Medical College.

Alfred George Patrick Thomson, M.B., C.M. Edinburgh, Edinburgh University and Manchester University.

Arthur Lisle Ambrose Webb, captain R.A.M.C., L.R.C.P., M.R.C.S., Royal Army Medical College and University College Hospital.

Royal Colleges of Physicians and Surgeons Edinburgh, and Faculty of Physicians and Surgeons, of Glasgow.

The quarterly examinations of the above Board, held in Edinburgh, were concluded on January 29th, with the following results:—

First Examination, Five Years' Course.—Of 33 candidates entered, the following 19 passed the examination:—David Laurance Brown, Glasgow (with distinction); Abdul Majid Shah, Patiala; William Tilden Lawrence, New York; Charles Langley Ievers, Co. Clare; Shankar Pandurang Gogte, India; Behram Shapoorji Photographer, Bombay; Madan Lal Puri, India; Edith Huffton, Madras; Hamilton Hoyland, Ipswich; Conrad James Arthur, West Indies; Shivnarain Rozdon, India; Shridhar Chintaman Jog, India; Surendra Kumar Sen, India; Henry Gilbert Lamberty, Mauritius; Rajanja Sivasubramanya Aiyar, Madras; Cuverji Ruttonji Vevai, Bombay; Hiralal Keshavlal Nanavati, Junagadh; Framroz Maneckji Vajifdar, Aden; and Shivshankar Ramchandra Soneji, Bombay; and 3 passed in physics, 1 in biology, and 4 in chemistry.

Second Examination, Four Years' Course.—David Dewar McNeill, Orkney, passed the examination.

Second Examination, Five Years' Course.—Of 25 candidates entered, the following 11 passed the examination:—Angus Cameron Livingston, Glasgow; Daniel Hickey, Co. Cork; Walter Crosse, Liverpool; Shivnarain Rozdon, India; Richard Fraser Lunn, Edinburgh; Abdul Majid Shah, Patiala; John Alexander Irwin, Co. Donegal; Thomas Brownlie McKendrick, Wishaw; Albert Robert Henry Harrison, Berehaven; Denis Cogan, Co. Cork; and James Noonan, Ireland; and 2 passed in physiology.

Third Examination, Five Years' Course.—Of 40 candidates entered, the following 22 passed the examination:—Maurice Fitzgerald Anderson, Rosewell (with distinction); Edward Roland Porter, Belfast (with distinction); James McTurk, South Wales; Charles James Faill, Edinburgh; William Cape Doughty, London; John McKelvey, Belfast; Bhairawnath Dinanath Khote, Bombay; John David Jones, North Wales; Cuverji Ruttonji Vevai, Bombay; Thomas Boston Johnstone, Edinburgh; Alfred Benjamin Bateman, Cork; George Lindsay Irwin, Co. Donegal; Shankar Pandurang Gogte, India; Lionel Wilson Bradshaw, Wakefield; Shivshankar Ramchandra Soneji, Bombay; Franklin Joseph de Souza, India; James Barlow Barnes, Bolton; Hiralal Keshavlal Nanavati, Junagadh; Thomas Walsh, Sheffield; Thomas McClure, Ireland; Edward Peake Maitland, India; and Crichton Raoul Merrillees, Victoria; and 3 passed in materia medica.

Final Examination.—Of 82 candidates entered, 33 passed the examination and were admitted L.R.C.P.E., L.R.C.S.E., and L.F.P. and S.G.:—William Rollin, England; George Edward Peckett Davis, British Guiana; William Linton Watson, Midlothian; Daniel Kennedy, Cork; Herbert Moncrieff Sturrock, Edinburgh; Herbert Charles Orrin, Colchester; John Phelan MacDonald, Canada; Robert Marmaduke Riggall, London; Tiruvarur Arunachala Ramaswami Aiyar, India; Patrick Martyn O'Dwyer, Cork; Herbert Hoyle Whaite, Yorkshire; Horace Weldon Coutts, Canada; Nathaniel Moxon, St. Helens; Charles Gisborne Hurrey, New Zealand; Morgan Howard Howard-Jones, Newport; William Church Mann, Derry; Rajanja Sivasubramanya Aiyar, Madras; William Sunner Carter, Co. Kildare; William Harvey Bennett, Chester-le-Street; William Roberts Ellis, Bala; Thomas Wrenn Faulkner, Cooma, N.S.W.; Louis Joseph Patterson-Clavier, St. Lucia, W.I.; William Henderson, Scotland; Walter Langmuir Watt, Ontario; George Coats, Paisley; Lionel Christopher Wijesinha, Ceylon; Byramji Shavakshah Tarapurvalla, Bombay; Ellis Thomas Evans, North Wales; Alexander Paul Dias, Bombay; William Henry Curtis, Hampshire; John Smith Peebles, Dundee; Angus Cameron Mackay, Argyll; and Charles Andrew Lawrence, Darlington; and 8 passed in medicine and therapeutics, 2 in surgery and surgical anatomy, 15 in midwifery, and 8 in medical jurisprudence.

The Royal University of Ireland.

The Senate met on Friday last, February 1st, when the following were appointed Examiners in Medicine, &c., for the year 1907:—

Medicine.—J. A. Lindsay, M.D., J. F. O'Carroll, M.D.

Surgery.—T. Sinclair, M.D., M.Ch.

Pathology.—E. J. McWeeney, M.A., M.D., A. E. Moore, M.B., W. St. C. Symmers, M.D.

Midwifery.—Sir J. W. Byers, M.D., M.A.O., A. J. Smith, M.Ch., M.A.O.

Medical Jurisprudence.—P. T. O'Sullivan, M.D., A. Roche, M.R.C.P.I.

Materia Medica.—M. Dempsey, M.D., Sir W. Whitla, M.D.

Ophthalmology.—A. W. Sandford, M.D., M.Ch., I. Werner, M.B.

Physiology.—T. H. Milroy, M.D.

Diploma in Public Health.—Sir C. Cameron, C.B., M.D.

The Vice-Chancellor called attention to the Report recently published of the Royal Commission on Trinity College, Dublin, and the University of Dublin. After discussion it was agreed that the Senate should meet again on Wednesday, February 20th, for the further consideration of this matter.

NOTICES TO CORRESPONDENTS, &c.

☞ **CORRESPONDENTS** requiring a reply in this column are particularly requested to make use of a *Distinctive Signature or Initial*, and to avoid the practice of signing themselves "Reader," "Subscriber," "Old Subscriber," &c. Much confusion will be spared by attention to this rule.

REPRINTS.—Reprints of articles appearing in this journal can be had at a reduced rate, providing authors give notice to the Publisher or Printer before the type has been distributed. This should be done when returning proofs.

CONTRIBUTORS are kindly requested to send their communications, if resident in England or the Colonies, to the Editor at the London office; if resident in Ireland, to the Dublin office, in order to save time in reforwarding from office to office. When sending subscriptions, the same rule applies as to office; these should be addressed to the Publisher.

DR. H. N.—The point is an awkward one to advise upon at this moment, as it happens to be *sub judice*. A case was tried in London in which the telephone-tenant refused to pay a further year's rent after quitting his house, and the judge held that the Postmaster-General's agreement was harsh and inequitable. He therefore gave judgment for the tenant, thus overruling the wording of the agreement. An appeal has been entered. On the other hand, in other cases the tenant has always been made to pay.

THE FALLACY OF THE MUSCLES.

REFERRING to the annotation on this subject in our issue of January 23rd, a correspondent sends us

To the Editor of THE MEDICAL PRESS AND CIRCULAR.

SIR,—Big muscles are all very well in their way,
But they must be kept up to the mark;
A very short illness will rapidly tell.
And supply ample cause for remark.
The muscles get flabby or turn into fat,
And if the complaint should last long
You friends never tire to daily enquire,
Why take such a time to get strong?
Ah! Give me the clock with reliable works,
The case not so showy to see;
To *last* longer, than *look* so much stronger,
It's far more important for thee.

Yours, &c., A. D.

A SAD CASE.

WE are asked to insert the following appeal:—The widow of a medical man (M.R.C.P.Lond., and M.R.C.S.) formerly in excellent practice in the West-end of London, finds herself in her old age reduced to less than bare necessaries. All she has to depend upon is an annuity of £20 a year from a medical charity (which is sufficient to pay her rent), and 5s. a week given by her children, which is all they can possibly afford. The husband was compelled to relinquish his practice in consequence of a long and painful illness, unfortunate speculations completed his ruin, and he was unable to provide for his widow and family. The poor old lady, who is 81 years of age, is crippled with rheumatism in both knees and is only able to crawl about a very little. Her sight is very bad, and she is entirely unfit to do any sort of work. It is desired to raise a small fund out of which an allowance can be made to supplement her income. Communications should be addressed to Mr. Colin F. Campbell, Hon. Social Secretary of the Church Army, 55, Bryanston Street, London, W., who will gladly answer all inquiries.

THE DEATH-RATE *VERSUS* LIFE-RATE.

"**A REPORT** just issued shows that the death-rate for last year was the lowest on record. On the other hand, the rate at which we live is constantly increasing."—*Punch*.

S. W. G.—If it can be proved that the entries in the ledger of patients were fictitious, you could demand a return of your deposit and the cancelling of the agreement.

Meetings of the Societies, Lectures, &c.

WEDNESDAY, FEBRUARY 6th.

OBSTETRICAL SOCIETY OF LONDON (20 Hanover Square, W.).—8 p.m.: Annual Meeting. Specimens will be shown by Mr. J. Bland-Sutton, Mrs. Boyd, Mr. Doran (for the late Dr. G. B. Ferguson), and Dr. Tate. Annual Address: The President (Dr. Dakin).

MEDICAL GRADUATES' COLLEGE AND POLYCLINIC (22 Chenies Street, W.C.).—4 p.m.: Mr. J. Pardoe: Clinique. (Surgical). 5.15 p.m.: Lecture:—Dr. E. Cautley:—Constipation in Infancy and Childhood.

NORTH-EAST LONDON POST-GRADUATE COLLEGE (Tottenham Hospital, N.).—2.30 p.m.: Cliniques:—Dermatological (Dr. Meachen), Ophthalmological (Mr. Brooks), Medical Out-patient (Dr. Whipham). 4.30 pm.: Lecture:—Mr. R. P. Brooks: Ocular Headaches.

THURSDAY, FEBRUARY 7th.

NORTH-EAST LONDON CLINICAL SOCIETY (Tottenham Hospital, N.).—4 p.m.: Discussion on the Sequelæ of Influenza (opened by Dr. M. Leslie).

MEDICAL GRADUATES' COLLEGE AND POLYCLINIC (22 Chenies Street, W.C.).—4 p.m.: Mr. Hutchinson: Clinique. (Surgical) 5.15 p.m.: Lecture:—Dr. F. J. Smith: Some New Ideas on the Old Subject of Indigestion.

NORTH-EAST LONDON POST-GRADUATE COLLEGE (Tottenham Hospital, N.).—2.30 p.m.: Gynæcological Operations (Dr. Giles), Cliniques: Medical (Dr. Whiting), Surgical Out-patient (Mr. Carson). 3 p.m.: Clinique:—Medical In-patient (Dr. Chappel).

ST. JOHN'S HOSPITAL FOR DISEASES OF THE SKIN (Leicester Square, W.C.).—6 p.m.: Chesterfield Lecture:—Dr. M. Dockrell: Syphilis as it modifies other Eruptions of the Skin: Symptoms, Diagnosis, and Treatment.

FRIDAY, FEBRUARY 8th.

WIMBLEDON AND DISTRICT MEDICAL SOCIETY (Worple Hall, Worple Road, Wimbledon).—9 p.m.: Paper:—Mr. R. Johnson: Acute Bone Suppurations in Children.

CLINICAL SOCIETY OF LONDON (20 Hanover Square, W.).—8.30 p.m.: Papers:—Dr. F. Hawkins: A Case of Typhoid Fever, with Acute Pneumonia, Pericarditis, and Hæmorrhagic Pleural Effusion. Mr. J. R. Lunn and Dr. G. Holmes: Clinical and Post-mortem Notes of a Case of General Paralysis of the Insane in a Boy. Dr. M. Fletcher and Mr. B. Robinson: Further Report of a Case of Idiopathic Dilatation of the Colon.

MEDICAL GRADUATES' COLLEGE AND POLYCLINIC (22 Chenies Street, W.C.).—4 p.m.: Dr. J. Horne: Clinique. (Throat).

NORTH-EAST LONDON POST-GRADUATE COLLEGE (Tottenham Hospital, N.).—9.30 a.m.: Clinique. Surgical Out-patient (Mr. H. Evans). 2.30 p.m.: Surgical Operations (Mr. Edmunds). Cliniques:—Medical Out-patient (Dr. Auld), Ophthalmological (Mr. Brooks). 3 p.m.: Clinique:—Medical In-patient (Dr. Leslie).

Vacancies.

The Royal National Hospital for Consumption and Diseases of the Chest, Ventnor, Isle of Wight.—Assistant Resident Medical Officer. Salary £100 per annum, with board and lodging in the Hospital. Applications to the Secretary, 34 Craven Street, Charing Cross, London.

Newcastle-upon-Tyne and Northumberland Sanatorium for Consumption, Barrasford-on-Tyne.—Resident Medical Officer. Salary £180 per annum, with board and laundry. Applications to Secretary, 13 Grey Street, Newcastle-upon-Tyne.

King Edward VII. Sanatorium, Midhurst, Sussex.—Junior Assistant Medical Officer. Salary £100 per annum, with board, lodging, and attendance Applications to the Hon. Secretary, 19 Devonshire Street, Portland Place, London, W.

Glasgow District Asylum, Gartloch, Gartcosh.—Resident Assistant Medical Officer. Salary £125 per annum, with board and lodging. Applications to the Medical Superintendent.

Bath Royal United Hospital.—Resident Medical Officer. Salary £100 per annum, with board, lodging and washing. Applications to J. M. Sheppard, F.C.I.S., Secretary.

The House of Recovery and Fever Hospital, Dublin.—Junior Assistant Resident Medical Officer. Applications to John Marshall Day, Medical Superintendent. (See advt.)

Appointments.

ARNELL, EDWARD, L.R.C.P.I., M.R.C.S.Eng., D.P.H., Medical Superintendent of the Newton Abbot Joint Hospital District, Devon.

BLUCKE, HENRY FREDERICK STOKES, L.R.C.P., M.R.C.S., Medical Officer of Health of Shaftesbury, Dorset.

CANN, FRANCIS JOHN HUGHTREDE, M.B.Lond., L.R.C.P., M.R.C.S., Honorary Medical Officer to the Dawlish Cottage Hospital.

CHEATLE, C. T., M.R.C.S., L.R.C.P.Lond., Certifying Surgeon under the Factory and Workshop Act for the Burford District of the county of Oxford.

COPLANS, MYER, M.D.Lond (State Medicine), D.P.H.Camb., Demonstrator of Bacteriology in the Faculty of Medicine of the University of Leeds.

ELDER, DOUGLAS, M.B., Ch.B.Liverp., Pathologist to the King Edward VII. Sanatorium, Midhurst, Sussex.

FENTON, W. J., M.D.Cantab., M.R.C.P.Lond., Assistant Physician to the Hospital for Consumption and Diseases of the Chest, Brompton.

HUDSON, ARTHUR, L.R.C.P., M.R.C.S., D.P.H.Camb., Honorary Medical Officer to the Dawlish Cottage Hospital.

LAWRENCE, C. J. MONTAGU, L.S.A., Junior House Surgeon at the Borough Hospital, Birkenhead.

LOVELY, CHARLES NEWTON, M.D., B.S.Durh., Honorary Medical Officer to the Dawlish Cottage Hospital.

RAWES, LESLIE, M.R.C.S.Eng., L.R.C.P.Lond., Junior Resident Medical Officer at the Royal Waterloo Hospital for Children and Women.

ROBINSON, H. BETHAM, M.S.Lond., F.R.C.S., Surgeon to St. Thomas's Hospital.

SAWARD, A. H. M., M.R C.S., L.R.C.P.Lond., Certifying Surgeon under the Factory and Workshop Act for the Richmond District of the county of Surrey.

STEVENS, WILLIAM MITCHELL, M.D.Lond., M.R.C.P.Lond., M.R.C.S., Honorary Consulting Physician to the Royal Hamadryad Seaman's Hospital, Cardiff.

STUART, HACKWORTH, M.D.Lond., F.R.C.S.Eng., D.P.H.Cantab., Medical Officer to the Staffordshire County Industrial School, Werrington, Stoke-on-Trent.

Births.

ADDISON.—On Jan. 30th, at Pretty Corner, Northwood, the wife of Christopher Addison, M.D., F.R.C.S., of a daughter.

MATTHEWS.—On Jan. 31st. at Wheathouse Road, Huddersfield, the wife of Craufurd Tait Matthews, M.B., of a son.

SILVER.—On Dec 10th, at Bermuda, the wife of Major J. P. Silver R.A.M.C., of triplets (girls).

Marriage.

CLOVER—ALEXANDER.—On Jan. 31st, at the Parish Church, Watford, Harry, youngest son of the late Joseph Thomas Clover, F.R.C.S., and of Mrs. Clover, of 16, Devonshire Terrace, Hyde Park, W., to Elsie Margaret, younger daughter of John Alexander, of Glendale Cassio Road, Watford.

Deaths.

MURPHY.—On Jan. 22rd, at Cork, Harriet Normand, widow of the late Surgeon-General M. W. Murphy, A.M.S., and third daughter of the late Henry Normand, Dysart.

COCKEY.—On Feb. 3rd, at 20, Somerset Road, Frome, Selwood Edmund Cockey, M.R.C.S.E., in his 90th year

THE MEDICAL PRESS AND CIRCULAR.

NOTES AND COMMENTS.

A Nervous Practitioner.

THE Thaw trial in America presents very little that is remarkable except the power of wealth, and the vulgarity of certain sections of society in that country and this. There is no mystery to be unravelled, and no legal difficulty to be solved. The murder was of the most prosaic and commonplace description, and if the persons concerned had not been both in affluent circumstances and connected with showy society, the mere fact would not have been worth chronicling in the British press. As it is, the only possible defence is one of insanity, and that only could be regarded as valid on the assumption that crimes of jealousy are all expressions of mental derangement. Surely no medical witness ever cut a more pitiable figure in the box than Dr. Wiley, the family doctor of the Thaw family. Mr. Jerome, the counsel for the prosecution, is credited with great ability for the way he riddled his evidence, but for ourselves we can only say that he had an uncommonly easy victim. In answer to Thaw's counsel, Dr. Wiley said he had devoted much of his life to the study of insanity, that he had acted as expert in a large number of cases, and that he was connected with the Dixmont Insane Asylum. As an expert, and from personal observation, he believed that Thaw was insane. Of Dr. Wiley's claim to be an expert, Mr. Jerome had little difficulty in disposing. The "expert" confessed he did not exactly know what Romberg's sign was; he did know the Argyll-Robertson pupil, but was not sure where he had heard of it, and he thought Argyll and Robertson were two different men! When asked what line of practice he followed, he described himself as a "nervous practitioner"—a statement that would lead us to the conclusion that neurology must be at a remarkably low ebb in Pittsburg. Indeed, since the days of Arthur Orton and the *pons asinorum*, we have heard nothing comparable to the ignorance of elementary facts displayed by this nervous practitioner.

Not Wily.

CONSIDERING that the defence has unlimited funds on which to draw, and that it commands the highest legal talent in America, it is almost incredible that such an "expert" should have been called as the principal witness, and moreover that it was never arranged for him even to examine the prisoner. It is not to be wondered at that Dr. Wiley's departure from the box was the signal for a breeze among Thaw's counsel, and that the plea of insanity was dropped like a hot copper. We know that there is little enough comprehension on the part of lawyers in this country as to what lunacy really is, but if the incident under notice is at all typical of what passes for expert evidence of insanity in America, the respect of lay people for medical knowledge of morbid psychology may justifiably be exceedingly slight. The "nervous practitioner"—a term which we take it was meant to signify a medical man practising as a specialist in nervous diseases—admitted that he had not extensively studied pyschology, but said he did know what was meant by the word. For the credit of American medicine, which has a justifiably high reputation, it is charitable to assume that Dr. Wiley was more nervous as a witness than as a practitioner, and that he really did not know what he was saying in reply to Mr. Jerome. A well-known surgeon in London confessed in Court the other day that the opposing barrister could make him say anything he (the barrister) wished, and perhaps Dr. Wiley was similarly artless. But the incident is inexpressibly humiliating to those who have the credit of the profession at heart.

Tonic Eggs.

WE have it on the authority of no less an expert than the late Dan Leno that eggs are divisible into three classes—fresh eggs, eggs, and eggs for electioneering purposes. To these must now be added a fourth, namely, medicinal eggs, that is, eggs which combine curative virtues with the usual nutritious qualities. The inventor, or breeder—it is difficult to know quite which is the correct term—of these pharmacopœial novelties is one Austin Goodyear Brown, a poultry farmer, of Lakewood. U.S.A. This gentleman conceived the idea that certain medicines might be made more palatable and eggs rendered of higher dietetic value if his hens were fed on tincture of iron, arsenious oxide, phosphate of lime, and similar medicaments. His early experiments—or "provings," as the homœopathics would say—were of an interesting, but rather disastrous character. In the drinking-pans of his hens he inserted small quantities of arsenic, and the intelligent birds, realising that great things were expected of them, exhibited great mental and bodily activity; they became very bright and active, ate ravenously, and laid eggs with extraordinary vigour. But, alas, the limits of avian physiology are not indefinitely extensible, and at the end of the week the hens were all dead. Undaunted by failure, Mr. Goodyear Brown started feeding twenty promising pullets on smaller doses of arsenic, and soon had the satisfaction of raising a brood of beautiful birds, who not only laid eggs, but laid arsenicated ones.

Fowler's Solution. SEEING that in Great Britain the difficulty is to keep arsenic out of beer, wall-papers, and other articles of domestic use, it seems rather gratuitous to attempt to introduce that metal into eggs, but Mr. Goodyear Brown finds these delicacies in request for ladies with sallow complexions and for sufferers from chorea and malaria. Indeed, jaded society belles are journeying to Lakewood to undergo the egg cure, and phosphatised eggs are reputed to be doing great things in the way of replenishing neurasthenic tissue and hysterical nerves. Far be it from us to condemn therapeutic enterprise, but the thought suggests itself that the dosage *per ovum* must be more than a little empirical, and though this may be a small matter in regard to phosphate of lime, or even tincture of iron, there seems to be some danger lest the patients who take this arsenic in the vitellised form may share the fate of the first batch of hens. Still, we may contain our souls in patience, for the magic egg is not likely to find its way to this country till the conditions of administration have been determined by experiment on our fair cousins, and if in the meantime we lay ourselves open to the reproach of being prejudiced and "behind the times," we may be on safer ground in adhering to the old and tried methods till such time as the term, "Fowler's solution" acquires another and more pregnant signification.

Legitimate Commissions. IT is unhappily our lot frequently to have to call attention to the puerile ignorance of County Court judges in relation to medical matters; indeed, it would be almost correct to say that that type of functionary seems endowed with an abnormal capacity for making itself ridiculous when called on to make a decision in questions affecting medical men. Our attention has been directed to a glaring case illustrating this principle of British law by the letter of a correspondent, which will be found in our correspondence columns this week. Last month, Dr. G. E. J. Crallan, the honorary secretary of the Association of Medical Men Receiving Resident Patients, had occasion to summon a member of the Association for failure to pay commission on a patient received into his house. Of the member's liability in law we have not sufficient evidence to speak decisively, but if we accept the judge's decision that the medical man in question was not shown by the evidence to be liable, we are utterly at a loss to understand his remarks in giving judgment. He said: "An association of professional gentlemen which, by its rules, stipulated for the payment of commission on sums received in respect of the patients was somewhat of a novelty. It was not his duty to act as censor, but he was by no means convinced that such associations or such stipulations as these deserved encouragement."

Self-Help or Agents. Now the Association referred to is composed of medical men who either do not practise in the ordinary way, or who seek to help to pay their way in the early years of practice by receiving resident patients into their houses, and in order to save the expense of individual advertisement and mutually to aid each other, they form a straightforward association free to anyone seeking the particular class of work dealt with, and staffed by honorary officers, to organise the placing of patients, and to give invalids wishing to reside with doctors information as to medical men who can offer accommodation likely to meet their requirements. Till the formation of the Association the work was done by lay agents who made a good profit out of the medical men who subscribed to their businesses and paid commission on fees from patients received. In a word, this Association is a defensive agency in which any profits arising from subscriptions and commissions is used for the common benefit, and as long as it is honestly managed and well conducted, as has always been the case, such a combination is perfectly honourable and legitimate. By means of it medical men are able advantageously to place patients with their colleagues in different parts of the country, and the members of the Association are assured of impartial treatment. So that for Judge Philbrick to offer comments such as those quoted displays a degree of ignorance, if he did not acquaint himself with the facts, or of impertinence if he did, which is equally blameworthy in a person holding his position of authority.

LEADING ARTICLES.

THE CEREBROSPINAL FEVER EPIDEMICS.

PUBLIC attention has been of late markedly drawn to the somewhat rare disease known popularly as "spotted fever," and scientifically as "cerebrospinal meningitis." The Belfast epidemic appears to be recurring as well as that in Glasgow, while the malady has recently invaded Edinburgh. At this juncture the medical officer of Glasgow, Dr. Chalmers, has published a valuable and timely report on the deaths attributed to meningitis in that city during the past six years. The most salient feature of his report is the fact that during the year 1906 the fatal cases referable to diseases of the central nervous system exceeded the six years' average by 136. This result was due to an increase of 63 under tubercular meningitis, and 147 ascribed to cerebrospinal fever, as against a reduction of 74 from simple meningitis. Dr. Chalmers has done well in insisting upon the need of great care in investigating cases before attributing them to the epidemic form of the disease. Compulsory notification is not provided for under the Act of 1889, but there is little difficulty in obtaining information from medical practitioners when they are aware of the incidence of cerebrospinal meningitis in their neighbourhood. The spread of the disease is rapid. On the first day of the present month no less than 63 cases, with three deaths, were intimated to Dr. Chalmers. He found the mortality, roughly speaking, about 70 or 80 per cent. of cases, but the case mortality is usually given as varying from 30 to 60 or 70 per cent. During the second week of January of the present year a considerable increase began in the number of cases registered. The exact figures for the three weeks ending February 2nd were 32, 32, 28 and 28 respectively. The age incidence of epidemic cerebrospinal meningitis is a striking feature. About 50 per cent. of cases occur under five years of age, and another 30 per cent. under ten years, while the rest may appear at any age up to forty-five or fifty. The name "spotted' which is so widely used by the laity, is curiously inappropriate, as it points to a by no means common characteristic of the attack. The origin of the malady is now generally recognised in the *diplococcus intracellularis meningitidis*, but it is not always to be found, especially in the later stages. This specific organism sets up inflammation in the membranes of brain and cord, and gives rise to a train of severe symptoms that present a well-marked clinical picture—the sudden onset with severe vomiting, headache, restlessness, retraction of head, squint, twisting of the face, pain all over body, fever, rash, and general and local disturbances. The specific pathogenic organism may usually be obtained by drawing off some of the cerebrospinal fluid by means of a lumbar puncture. It appears to be commonly conveyed through the milk of the nursing mother. A great deal, however, remains to be learnt with regard to the exact habitat and transmission of this specific microbe. Dr. Chalmers gives an interesting warning with regard to one possible channel of distribution as follows :—" In households where cases occur it should be remembered that discharges from the mouth, nose and ears have been associated with the occurrence of the disease in former outbreaks elsewhere." His advice generally as regards infection shows plainly enough that our scientific knowledge is not yet adequate in that direction. After warning parents against exposing children against sudden variations of temperature, he insists upon the necessity of a " rigid observance of absolute cleanliness of everything which may be placed in the mouths of young children, whether for food or other reasons." We are happy to be able to refer our readers to two articles on the subject published elsewhere in our columns. One is from the pen of Dr. William Elder, who has had several cases under his care at Leith Hospital during the past few months. The other is an interesting account of two fatal cases by Drs. John Thomson and Stuart McDonald, of Edinburgh. In conclusion, it may be remarked that Government would do well to spend any amount of money that might be required to investigate fully the facts concerned with epidemic cerebrospinal meningitis. The cost of such an enquiry would be trifling compared with the vast sums continually sunk in unproductive expenditure, and should be regarded in the light of a national investment.

SIR EDWARD BRABROOK presided on Monday afternoon at a special meeting of the Council of the Charity Organisation Society held at Denison House, Vauxhall Bridge Road, where a discussion on "Health Visiting in Relation to Infant Mortality" took place.

CURRENT TOPICS.

Servants' Insurance and Medical Examination.

HOUSEHOLDERS throughout the Kingdom are becoming anxious at the near approach of the day of full responsibility for accidents and illness arising from employment among their domestics. Hardly one of them has not anxiously scanned the terms offered by the various insurance companies who are bidding for the coming harvest of servants' insurance. One aspect of the new situation, however, appears to have hitherto escaped the keen scrutiny alike of employers and employed as regards insurance in this particular form of service. Obviously, the halt and the maimed, the sick and the feeble, will run infinitely greater chance of sustaining injury in the course of their occupation. It will be absolutely necessary, therefore, for the protection not less of the insurance companies than of the employers, to have a certificate of the bodily health of domestic servants before insurance. This duty must fall upon the medical profession, who will do well to adopt at once and decisively a uniform fee, say, of five shillings for each certificate. Unless the medical profession take a firm stand in the matter it is likely to find itself saddled with yet another medical certificate granted to the public free, gratis, and for nothing.

The First Garden City.

The annual meeting of the First Garden City (Limited) was held last week, and the report presented to it was of a most encouraging character. The boldness of the experiment is being slowly but surely justified by the success of its practical working, and as it is an experiment of first-class importance from the point of view of the public health, medical men generally will be delighted to hear that it is making excellent progress. In the last year the population has almost doubled, and there are now some three thousand inhabitants dwelling on the estate. The value of buildings erected has risen from £90,000 to £237,000 ; the Howard Memorial Hall has been opened, and other public buildings are under construction. A number of important firms, including Messrs. J. M. Dent and Co., the publishers, Messrs. W. H. Smith and Son, the Arden Press, Ltd., and the Garden City Embroidery Co., have taken sites for works, and the Heatly-Gresham Engineering Co., Ltd., have doubled the size of their buildings and increased their staff from eighty to two hundred persons. Moreover, the Great Northern Railway has taken fourteen acres for a goods yard—a sure sign of progress—and the Garden City Gas Company have been able to show a profit on the year's work. Unfortunately, as regards profit to the promoters of the Garden City Company itself, it is yet too early to speak, but though the working expenses exceed the income, the increased value of the land will soon now turn the concern into a really valuable asset, and when a valuation is made, as is about to be the case, it will probably be found that the Company is in a financially sound position. But the chief feature is that ultimate success is now assured; the population, the capital, and business enterprises are being attracted, and it will not be long before the Garden City is a self-contained community in which the condition of the poorest and weakest will be secured against encroachment and the best known modern conditions of healthiness assured to all. In so far as example is better than precept, so are the founders of the Garden City superior to those social reformers who talk much and do nothing.

Hospital Saturday Fund.

OF all the Metropolitan funds, the Saturday deserves the hearty support of the medical profession, inasmuch as its executive is representative of hospital charities, great and small, as well as of the class from which hospital patients are drawn. The result is that the Saturday distribution grants are often opposed in policy to those of the Sunday and the King Edward Funds. It may be fairly assumed that the support of any given institution by representatives of its *proteges* is a fairly good test of its usefulness and popularity. Certainly patients are more likely to be judges upon such a point than wealthy benefactors and professional philanthropists, who know little or nothing of what goes on behind the scenes in hospital life. The only suggestion we can offer the Saturday Fund is that the ranks of the medical profession be represented, as apart from the members of the honorary medical staffs of a few favoured large London hospitals who sit on the executive boards of the other two funds mentioned. Broadly speaking, at present the smaller hospitals get scant justice at the hands of any but the Saturday Fund. Both the Sunday and the King Edward Funds, by withholding a grant, may cast an absolutely undeserved stigma upon any institution, simply because it is small and struggling. Nor need they give any hint or explanation as to their action. They are essentially autocratic, irresponsible, and non-representative bodies, and as such lag hopelessly behind the times.

Mr. Bryce's Irish University Scheme.

A PERUSAL of the volume of evidence taken by the recent Commission on Dublin University, which appeared last week as a Blue Book, cannot fail to be interesting to everyone concerned with higher education in Ireland. Careful study of it, however, still leaves undiscovered any cogent arguments in favour of Mr. Bryce's scheme now before the country. The great weight of the evidence was against any tampering with Dublin University as at present constituted, beyond making certain important domestic reforms. All the witnesses representing the existing institutions expressed themselves strongly against such a plan as has now been put forward by Mr. Bryce, while most of those who pressed for the establishment of a new college were quite as satisfied to accept one in the Royal University as in Dublin University. In fact, the only witness who strongly urged the federal scheme was Lord Dunraven, who appears in this as in other matters, to be content to act as the mouth-piece of hidden powers. His authority in matters of education is, however, not apparent. For the proposed degradation of the Queen's College, Galway, no shadow of justification appears in the evidence. Except for one casual remark, by the Dean of St. Patrick's, there is practically no reference to Galway outside the evidence of its President. The truth is that the Arts School in Galway both in its present staff and in its past record is no way behind that in either Cork or Belfast, whereas to its medical school many distinguished Irishmen both at home and abroad owe their professional education.

Inspection of Restaurants.

An excellent example has been set to sanitary authorities by the Westminster City Council in taking vigorously in hand the inspection of bakehouses and restaurant kitchens. The bulk of the West End restaurants are situated in the area over which the Westminster Council exercises jurisdiction, and though it may be presumed that the high-class establishments which provide luncheons and dinners at half-a-guinea and seven-and-sixpence a head maintain something approaching decency and cleanliness in the kitchen domain, it is equally certain that a great many of the smaller foreign restaurants and workmen's eating-houses are filthy beyond description. The patrons of such houses are content to consume their meals, asking no questions for fear that their appetite might be impaired, but it certainly is the duty of public authorities to see that disease is not disseminated through the food and drink dispensed. The Westminster Council have now drawn up a series of rules and appointed special inspectors for all public restaurant kitchens for their district. These measures are such as will commend themselves to those who have the sanitary interests of the community at heart. The rules concern the structure and capacity of the kitchen, the drainage of the scullery, and the ventilation of the premises. No food is to be stored in any place where it may be exposed to infection or contamination; proper enamelled stoneware sinks are to be provided for washing vegetables in; all tables and benches are to be provided with wheels so that they may be easily moved, and shelves are to be fitted two inches from the walls, so that dirt shall not collect in corners. The employés are to have separate places for hanging their outdoor clothes, and every part of the premises is to be adequately lighted. If on this basis a sufficient staff of inspectors can secure "general cleanliness" of vessels and—let us add—the hands of cooks and waiters, the meals provided by the restaurants will taste none the less delicately, and they will certainly be distinctly less liable to produce gastric and intestinal disturbances in those who partake of them.

Personal Freedom o Public Officers.

A principle of great importance is at stake in the struggle which has been going on between the Medical Officer of Health and the City Council of Coventry. It appears that the Medical Officer of Health, Dr. Snell, is also Honorary Secretary of the local branch of a medical association, and in the latter capacity he came into collision with the management of a provident dispensary, which thereupon appealed to the City Council as to whether Dr. Snell's continuance as honorary secretary was in accordance with the wishes of the Council and with the due discharge of his duties as their officer. The Council appeared to think the duties of the two posts incompatible, and the matter eventually came before the Local Government Board. That sapient body in the course of a long letter explain that they do not object to Dr. Snell's occupying his leisure time as he thinks fit, so long as his occupation "did not prejudicially affect the due discharge of his official duties, or bring him into inconvenient conflict with the Council or their constituents." In reply, Dr. Snell relates that the "due discharge of his official duties" has on many occasions brought him into conflict both with the Council and their constituents. Last year, for instance, he reported to the Local Government Board the occurrence of an epidemic, with the deaths of seventy children, due to neglect on the part of the Council, after repeated warnings. He had also on various occasions to enforce the law against individual members of the Council. We congratulate Dr. Snell on the stand he has made against an overbearing piece of tyranny. The freedom of personal action in the case of employés of all public corporations must be secured at all hazards.

Cerebrospinal Fever in Belfast.

Considerable alarm has been caused in the north of Ireland by the outbreak of cerebrospinal meningitis which has appeared there during the past few weeks. The total number of cases is said to be nearly fifty, and the deaths over twenty. The disease appears, therefore, to be of a virulent type, and in several cases deaths have supervened on a few hours' illness. Of one family of five children four succumbed inside the space of twenty-four hours' Another victim was a medical student of the Queen's College, whose death also occurred very rapidly. The Public Health authorities are doing all in their power by means of isolation to stay the progress of the disease. There is, however, no disease in the face of which medical skill is more powerless, either in the way of prevention or of cure. Of the natural history or habits of the causal organism nothing is known, while treatment is only symptomatic. We can only hope that the present outbreak may be speedily stayed, and if any further knowledge of the disease should result from a study of its appearances in Belfast, then even the serious loss of life will not have been in vain.

PERSONAL.

Dr. James Taylor will preside at the dinner of the Edinburgh University Club of London, which will be held at the Criterion Restaurant on February 20th.

Dr. Theodore Thompson, M.A., M.D. (Cantab.), M.R.C.P., B.Sc. (Lond.), F.R.C.S. (Eng.), has been appointed an honorary physician at the London Hospital.

Mr. Frederic Eve, surgeon to the London Hospital, has been re-elected, and Mr. J. Ernest Lane, surgeon to St. Mary's Hospital, has been elected a member of the court of examiners of the Royal College of Surgeons.

At a meeting of the board of management of the Chester Infirmary on February 5th, a letter resigning his post of honorary surgeon was received from Dr. James Taylor.

Dr. Peter Reilly O'Connell, Surgeon to the Mater Infirmorum Hospital, Belfast, has been appointed High Sheriff for Belfast for the year 1907.

The report that Professor Behring had entered an asylum is declared by his relations at Capri to be unfounded.

Major Leonard Rogers, I.M.S., will deliver the Milroy Lecture at the College of Physicians on February 21st, 26th, and 28th on "Kala-Azar: Its Differentiation and Epidemiology."

Dr. Herbert E. Roaf, the recently-appointed senior demonstrator of physiology in the University of Liverpool, has intimated his intention to resign the research scholarship he held in connection with the Science Committee of the General Medical Council.

Sir Alfred Jones presided at a meeting of the African Trade Section of the Chamber of Commerce on February 4th, when Dr. W. T. Prout, C.M.G. (late principal medical officer, Sierra Leone), delivered an address dealing with the health and sanitation of West Africa.

Dr. Donald Macalister, M.D., LL.D., D.C.L., Fellow and Director of Medical Studies of St. John's College, Cambridge, Linacre Lecturer of Physic, and President of the General Medical Council, has been appointed Principal of the University of Glasgow in succession to the late Principal Story.

Dr. Whitcomb, medical superintendent of the Birmingham asylums, was entertained to a complimentary dinner at the Queen's Hotel on February 4th by the Asylum Committee in commemoration of his having completed 25 years in the service of the city. An illuminated address, handsomely bound, was presented to Dr. Whitcomb.

Our Edinburgh correspondent informs us that it is now officially recognised—notwithstanding contradiction by the Press Association—that Dr. Donald MacAlister, President of the General Medical Council, has been appointed as new Principal of Glasgow University.

A petition has been received from the London School of Medicine for Women in reference to a proposal, now before the Council of the Royal College of Surgeons of England, that women should be admitted to the examinations of the college. It has been determined to inform the petitioners that the matter is receiving the consideration of the Council.

A telegram from Hull states that a Chinaman from the steamer "Dundas" from Bombay has died in the infirmary from beri-beri. Two others are in hospital, and another died on the voyage.

A CLINICAL LECTURE
ON
THE TREATMENT OF NON-MALIGNANT GASTRIC ULCER.

By SIR CHARLES BALL, M.Ch., F.R.C.S.I., Hon. F.R.C.S.Eng.,

Hon. Surgeon to His Majesty the King; Regius Professor of Surgery, University of Dublin; Surgeon to Sir Patrick Dun's Hospital.

A consideration of the causes which produce gastric ulcer and the conditions which tend to interfere with its healing when once established is obviously of first importance in deciding upon the best form of treatment to effect its cure.

The more or less circular outline, flat base, and sharp-walled edges of ulcer of the stomach are very special characters which at once suggest the operation of some special cause and the exposure of the stomach surface to a highly acid digestive fluid has been assumed to be the explanation. That the normal stomach is immune to auto-digestion is of course obvious. Weinland ("Halliburton's Handbook of Physiology," 6th edition, page 489) considers that this immunity is due to the formation by the stomach epithelium of an antipepsin, and that in the same way the intestinal epithelium forms an antitrypsin. If, then, the mucous membrane is injured by direct traumatism from hard substances swallowed, by septic infection from the ingesta, or by necrosis following embolic infarction, this theory supposes that auto-digestion occurs in the damaged area, and thus the ulcer is extended in dimensions and its healing is interfered with. This theory has received very general acceptation, so we see even in the most modern text-books the disease spoken of as "peptic ulcer of the stomach." I am confident that this is one of the somewhat numerous fallacies which have been adopted from time to time in medicine without question, although opposed to directly ascertainable facts. The evidence obtainable by *post-mortem* examinations, by clinical observation, and by surgical experience, clearly demonstrates that peptic action has nothing whatever to say to the origin or maintenance of gastric ulcer.

It is common to find at *post-mortem* examinations cicatrices in the stomach showing that gastric ulcers have undergone spontaneous cure. If auto-digestion had been the cause of these ulcers, how is it possible that the delicate process of healing by granulation and epitheliasation could go on while exposed to the same influence? It is notorious that a large proportion of cases of gastric ulcer get well under treatment by rest in bed, rectal feeding, and little or no fluid nourishment by the mouth. Physiologists tell us that gastric juice is secreted independent of the ingestion of solid food, that the sight of meat to a hungry dog causes a free flow, and that fluid meat extracts stimulate secretion. It is a popular expression that at the sight of dainty food the "mouth waters." It would alike be true to say that under similar circumstances the stomach juices.

Let us take now the case of a chlorotic girl lying in bed in hospital undergoing the routine treatment for gastric ulcer. Possibly in the next bed may be a case convalescent from some acute disease. When dinner hour arrives the convalescent is provided with a succulent mutton chop; the stomach case with a rectal injection, and possibly a tablespoonful of chicken broth. Our knowledge of physiology tells us that the latter must have a free secretion of gastric juice, which, not getting the coveted mutton chop to expend its energies on, might reasonably be expected to act more vigorously on the ulcer than if she had received a solid meal.

Surgical experience tell us that stomach wounds, when closely sutured up, heal with the utmost facility. It is usual in such wounds to bring the divided edges of mucous membrane together by a continuous silk suture, which must produce a certain amount of necrosis, and which eventually cuts its way out into the lumen of the stomach; surely under these circumstances, if gastric digestion of living stomach tissue ever occurred these wounds would not heal, or, at any rate, leakage would be of frequent occurrence, but we know that with proper modern technique leakage seldom or never occurs. This satisfactory healing of stomach wounds appears to indicate that the immunity against auto-digestion is not confined to the mucous membrane, but is present also in the deeper coats. The theory, therefore, of Weinland that the gastric epithelium forms an antipepsin appears to be scarcely a sufficient explanation.

A consideration of these facts renders the theory of peptic action as a cause of gastric ulcer quite untenable.

Septic infection, especially coming from suppuration in connection with bad teeth, has been suggested as a cause of gastric ulcer, and in all probability this may frequently be an initial element of the disease, but it is hard to imagine that it can be the cause of a chronic ulcer remaining open for months or years, especially when we see that gastro-enterostomy performed when there is an open ulcer in the stomach so rarely becomes infected.

The mechanical effect of solid food being churned about in the stomach is sometimes mentioned as the reason why gastric ulcers which may have had their origin in traumatism, sepsis, or infarction necrosis, do not readily heal, and although hitherto it has usually been considered as of secondary importance to the peptic theory, I am convinced that it is the true explanation, not only of the characteristic appearance of gastric ulcer, but also of the known facts relating to spontaneous cure and the results of medical and surgical treatment.

Many years ago, as a medical student, I saw an old surgeon make an issue in the back of a patient's neck for the treatment of severe facial neuralgia. A piece of adhesive plaster with a small circular hole in it was first applied, and caustic potash was rubbed in so as to produce a circular slough of skin where it was exposed in the hole in the plaster, When the slough separated an ulcer was left, and as the neuralgia had not been cured, the surgeon decided to "keep the issue open." This was done by the simple process of keeping a pea in the ulcer by means of a piece of adhesive plaster. By this method the issue could be kept from healing as long as considered necessary, and the characters of the ulcer thus produced with flat base and sharp-cut edges closely resembled the appearances we are familiar with in chronic gastric ulcer. As the pea kept the issue from healing, so the frequent passage of solid food over the surface of a gastric ulcer retards its cicatrisation.

We know that pain, sometimes very severe, follows the introduction of solid food into a stomach which is the site of ulcer. This may be so great that the patient instinctively avoids solids, and thus affords the stomach that rest which is necessary to permit of spontaneous cure.

Our modern treatment of gastric ulcer, which is quite unintelligible on the peptic theory, is readily explained if we believe that the continuance of ulcer is caused by the mechanical effect of solid food.

It is certain that a large proportion of cases of gastric ulcer will get quite well by rest in bed, rectal feeding, withholding solid food, and strict limitation of the amount of fluids taken by the mouth ; but it is well to remember that there are limits to this plan of treatment, and that if carried too far it will defeat its object, as there can be no doubt that a condition of semi-starvation seriously interferes with the healing process, and that surgical operations undertaken under these conditions are not satisfactory. I would strongly urge that all cases of uncomplicated ulcer of the stomach should in the first instance be treated by a short but efficient course of rest and limited diet, and that those cases which do not show rapid and marked improvement should be dealt with by surgical operation, and that cases of recurrence of symptoms after apparent cure by rest and limited diet should at once be operated on.

The operation now recognised as best in these cases is posterior gastro-enterostomy. Excision of the ulcer can only be practicable in a small minority of cases, and although it may occasionally in suitable cases be considered as an addition to gastro-enterostomy, it should not be undertaken as a substitute, as the essential object of surgical operation should be the provision of a free outlet from the lower portion of the stomach into the jejunum, the free exit thus provided for the contents of the stomach affording the ulcer the rest essential for its healing, and tending to prevent recurrence in the future. My personal experience of gastro-enterostomy and pyloroplasty extends to forty cases, but in only four of these was uncomplicated gastric ulcer found present. All the four recovered well, and so far as I know, remain quite free from recurrence. The results obtained by others who have had larger experience show that the dangers of the operation are comparatively trivial, and the proportion of cases in which complete cure follows is large, in many instances patients who for months or years have been in misery being made perfectly well.

The brilliant results of modern gastric surgery have tended sometimes to engender surgical recklessness. We occasionally hear of gastro-enterostomy being performed in purely neurotic cases, in the gastric crises of tabes, and even in dyspepsia due to chronic renal disease. Such proceedings do much to bring discredit upon this operation, which in properly selected cases is often such a conspicuous success.

The immediate risk of posterior gastro-enterostomy in ordinary cases is probably not more than 2 or 3 per cent. It is, however, necessary to consider certain results of the operation which occasionally give trouble, and which are directly consequent on making a free communication between the stomach and jejunum, and of these the most frequent is the regurgitation of duodenal contents into the stomach producing vomiting. The recurrence of vomiting after gastro-enterostomy is an interesting physiological problem. We are accustomed to believe that the act of vomiting is caused by, first of all, a closure of the pylorus followed by a reflex peristalsis forcing the stomach contents up the œsophagus. If, now, a gastro-enterostomy is present, and, as it is unprovided with any sphincteric apparatus, it is reasonable to expect that an attempt to vomit would empty the stomach into the jejunum rather than up the œsophagus. It is obvious that for vomiting to take place under these circumstances there must be an associated spasm in the intestine, and also probably in the voluntary muscles of the abdominal wall.

Regurgitation of duodenal contents into the stomach, followed by persistent vomiting, is, however, not so troublesome with modern surgical technique as it was formerly. Katzenstein (MEDICAL PRESS AND CIRCULAR, Dec. 6th, 1906) states as a result of his investigations, principally on experimental gastro-enterostomy in animals, that a flow of duodenal contents containing bile and pancreatic juice into the stomach is constant for a considerable period after gastro-enterostomy, and adopting the peptic theory of gastric ulcer, he suggests that the neutralisation of the gastric juice by the alkaline duodenal contents is the explanation of the good results obtained by gastro-enterostomy. It must, however, be remembered, as pointed out by Ewald, that it is unsafe to draw conclusions from the results of gastro-enterostomy in animals, as the horizontal posture in them favours the flow of intestinal contents into the stomach more than in the case of man ; moreover, it is common surgical experience that bilious vomiting following gastro-enterostomy can generally be stopped by putting the patient in the sitting posture and so facilitating drainage Should, however, regurgitant vomiting prove serious, lateral anastomosis between the two limbs of the loop of jejunum involved in the gastro-enterostomy will usually prove effectual. In two of my forty cases of gastro-enterostomy this was necessary.

Another after-complication of the operation is the occurrence of so-called peptic ulcer, sometimes leading to perforation, in the jejunum. An interesting paper by Dr. Watts in the "Johns Hopkins Hospital Bulletin" for July, 1903, deals with this subject. The author performed gastro-enterostomy on a dog, and three months after it died of perforating jejunal ulcer. A review of the literature of the subject shows that up to date on fourteen occasions similar ulcerations have been recorded in the human subject ; it is remarkable that they all have been recorded in Germany.

The question whether such ulcers are really peptic is an interesting one. Although the jejunum is normally immune to alkaline trypsine digestion, it is quite possible that it may not be, like the stomach, immune to acid pepsine digestion; it is also unaccustomed to the presence of large quantities of undissolved food, such as it must receive after gastro-enterostomy. It appears at present impossible to say which of those factors is the most operative; at any rate, its occurrence is so rare that it cannot be held to be a contra indication to operation in suitable cases.

A curious sequence to gastro-enterostomy, which I have not seen described elsewhere, occurred in one of my cases; the portion of jejunum corresponding to the stomach anastomosis became dilated to quite four times its normal size, forming a sort of secondary stomach, and produced obstruction by kinking of the distal portion of intestine, with continuous vomiting. A lateral anastomosis below the dilatation quite relieved the symptoms; this was done a year ago and the patient at present remains in good health. I am quite at a loss to account for this condition.

In conclusion, I would urge, after the fullest consideration of the risks of operation, both immediate and remote, that all cases of uncomplicated gastric ulcer which have had a reasonable trial of treatment by rest, and limited diet, without very marked improvement, should be subjected to gastro-enterostomy. There are, however, many points, both pathological and physiological, in connection with this most interesting subject which still require further elucidation.

NOTE.—*A Clinical Lecture by a well-known teacher appears in each number of this journal. The lecture for next week's issue will be by Wm. Alexander, M.D., F.R.C.S., Lecturer on Clinical Surgery, University of Liverpool; Surgeon to the Royal Southern Hospital, Liverpool, on "Hydronephrosis," with notes of an extreme case of that disease.*

ORIGINAL PAPERS.

NOTES ON CEREBROSPINAL MENINGITIS. (a)

By WM ELDER, M.D., M.B., F.R.C.P.EDIN.,

Physician to the Leith Hospital.

DURING the past few months the author had under his care five cases of this disease. Case I. was a girl, æt. 5, who was admitted to hospital in an unconscious condition, with a history of illness lasting for about twenty-four hours. She had marked head retraction, high fever, and vomiting. On lumbar puncture, turbid fluid escaped under considerable pressure. It contained numbers of diplococci with capsules, mostly extracellular, but a few in the cells. They were Gram-positive and had the character of pneumococci. Rienzi's antipneumococcic serum was injected, and subsequently the temperature gradually fell. Convalescence was slow, and was hindered by the development of a parotid abscess, but ultimately the child recovered, with complete deafness as a residuum of the meningitis. Case II., a boy, æt. 2, was admitted with the history that he had been unconscious for two days On lumbar puncture, turbid fluid containing leucocytes and Gram-negative diplococci was withdrawn. A crop of purpuric spots developed on the abdomen, back, and neck. The temperature was at first normal, and then rose to 102°–103°. Rienzi's serum was injected on two occasions, and convalescence was now established. The patient is, however, blind, though there are no changes in the fundi. Case III., a girl, æt. 9, admitted after a short illness, in much the same condition as the preceding patient, with all the usual symptoms of acute meningitis, and a hæmorrhagic rash on the neck and trunk. As before, Gram-negative diplococci were found in the turbid cerebrospinal fluid. The serum could not at the time be obtained, and the patient died in a few days. *Post mortem*, purulent leptomeningitis of brain and cord, with the diplococcus intracellularis, was found. Case IV. occurred in an adult, æt. 37. On the morning of admission he had vomited and complained of headache; he became unconscious in a few hours. He was extremely restless, pupils unequal, considerable rigidity of limbs. The fluid yielded by lumbar puncture contained the diplococcus intracellularis. It was Gram-negative. Although the patient was evidently dying, an injection of serum was given, but without avail. On *post-mortem* there was typical purulent cerebrospinal leptomeningitis. Case V. was a boy, æt. 2½, who took ill with fever, headache, and vomiting twenty-four hours before admission. He rapidly became unconscious, and had a convulsion. On admission he was cyanosed and collapsed, with Cheyne Stokes breathing. There was a purpuric rash. He died soon after admission. Lumbar puncture gave the same turbid fluid containing diplococci. On *post-mortem*, cerebrospinal meningitis was found. These five cases showed that cerebrospinal meningitis was epidemic in Leith. The symptoms of the condition might best be described as an exaggeration of what are seen in tubercular meningitis. The onset was sudden, and unconsciousness often supervened rapidly. The temperature was high, and the pulse very rapid. Purpuric spots are usually absent at the onset; probably many cases do not survive long enough to develop a rash. Lumbar puncture affords the only certain diagnostic. The meningococcus closely resembles both the pneumococcus and the gonococcus, but the pneumococcus may be distinguished from the others by being Gram-positive. Not all observers are agreed as to which particular diplococcus is responsible for these cases, some having ascribed them to the pneumococcus, others to the meningococcus. In the first case the organism resembled the pneumococcus, but Dr. Elder was not for this reason disposed to put it in a separate class for that reason. It seemed to him possible that they might really have to do with modifications of the same germ. Probably the pneumococcus and the meningococcus were at least allied, and just as we had sporadic and epidemic pneumonia, so we had sporadic and epidemic cerebrospinal meningitis. There was no evidence that the disease was infectious in the ordinary sense. The cases had come from all over Leith, and mostly from crowded, insanitary neighbourhoods. Two of his first cases had recovered, both after getting injections of Rienzi's antipneumococcal serum; in each case improvement was noticed after every injection. At the same time, in bad cases, the chance was small; no disease is so rapid and hopeless—indeed, in this respect it resembles acute fulminating septic peritonitis. Lumbar puncture always gave temporary relief; so did saline transfusion. Morphia was the most useful sedative.

(a) Abstract of Paper read before the Edinburgh Medico-Chirurgical Society. Feb. 6, 1907.

NOTE ON TWO FATAL CASES OF ACUTE MENINGOCOCCAL CEREBRO-SPINAL MENINGITIS IN YOUNG CHILDREN. (*a*)

BY JOHN THOMSON, M.D., F.R.C.P.EDIN.
Physician, Royal Hospital for Sick Children, Edin.,
AND
STUART McDONALD, M.B., F.R.C.P.EDIN.,
Pathologist, Royal Hospital for Sick Children, Edin.

CASES of non-tuberculous meningitis they had hitherto been accustomed to meet with might be divided into (1) those due to pyæmic infection, with strepto- and staphylococci, &c.; (2) acute pneumococcal meningitis; (3) chronic or sub-acute posterior basic meningitis. The last-named formed the majority, occurred mostly in young infants, and was due to a special diplococcus practically identical with the meningococcus of Weichselbaum. Within the last few months, and particularly within the last week or two, they had met with a fourth group—acute cerebro-spinal meningitis, in which the cerebrospinal fluid contained typical meningococci in large numbers. These cases were far more acute than the ordinary posterior basic form, as if due to a much more virulent type of organism. The constitutional disturbance was greater, the fluid withdrawn by lumbar puncture was turbid or purulent, and the duration was measured by days rather than weeks.

Case I.—A boy, æt. 3½, was admitted to the Sick Childrens' Hospital with a history of feverishness and vomiting, which had lasted for three days. On arrival in the Children's Hospital he was unconscious, lying with his limbs flexed, and greatly resenting any interferences. There was no eruption. The pulse was 152, respiration 52, and temperature 102°. The abdomen was retracted; spleen not enlarged. The neck was rigid and slightly retracted, superficial reflexes normal; flexor plantar response; kneejerks abolished. Well-marked Kernig and *tache cerebrale*. No paralysis of cranial nerves. On lumbar puncture, very turbid fluid was withdrawn, in which meningococci was present. The patient died soon after admission.

Case II.—Child, æt. 2 years 2 months, was admitted with history of feverishness and vomiting lasting two and a half days; there had been no convulsion. She was well-developed and nourished; the extremities were cold, and the lips cyanosed. No purpuric or herpetic rash was present. She was very drowsy, and lay on side with head retracted. Pulse 140, respiration 32, temperature 98.2°. There was marked catarrh of the mouth and pharynx; the secretion contained staphylococci only. Abdomen not retracted; spleen not enlarged. There was marked opisthotonos with head retraction. The plantar and other superficial reflexes were normal. Knee and Achilles jerks normal, Kernig's sign absent. No affection of cranial nerves. After admission the vomiting continued; the head retraction increased, but the limbs showed no rigidity. Lumbar puncture yielded about 3 cc. turbid yellow fluid, and greatly relieved the head retraction. The fluid contained meningococci. There was a decided polymorphous leucocytosis. The patient died shortly after admission. On *post-mortem* examination no cutaneous hæmorrhages were present. There was an acute leptomeningitis of the brain and cord. In the brain the cortex was affected as well as the base, and meningococci were detected in the exudate. The organisms were typically Gram-negative. The other organs showed evidence of an acute toxæmia; there was no pneumonia. Histological examination confirmed the above appearances. The exudate in the brain showed little fibrin, numerous polymorphs, and large mononuclear cells, many vacuolated and degenerating, but many also actively phagocytic towards the polymorphs. The organisms in sections were scanty. The heart showed cloudy swelling and some interstitial myocarditis. There was cloudy swelling and fatty change in the other organs. Films from the cerebrospinal fluid removed during life showed great excess of polymorphs, with large numbers of typical meningococci, many showing involution forms. Cultures of typical meningococci were obtained from this fluid, but Gram-positive forms of the organism occurred in the culture, and in subcultivations the organism became strongly Gram-positive. On cultivation on serum agar pointed diplococci very like pneumococci appeared, and at one time it seemed as though two organisms were present. In subsequent culture, however, the typical shape of the meningococci was regained, though the organism was strongly Gram-positive. The authors believed that they were dealing with a pure culture of meningococcus, and were confirmed in their opinion by the observation of a similar alteration in the staining characteristic of the organism derived from a more recent fatal case in the Childrens' Hospital. Bacteriologically, posterior basal meningitis and acute cerebrospinal meningitis are identical, only differing in degree. The authors suggested that attenuated meningococci might exist in the nasal and other secretions of many children, just as attenuated pneumococci might be found, and that under certain conditions these organisms might become virulent, giving rise to posterior basal meningitis, or, still more virulent, to the acute epidemic form of the disease.

INFANT FEEDING. (*a*)

BY ROBERT HUTCHISON, M.D., F.R.C.P., LOND.,
Assistant Physican at London Hospital and at the Children's Hospital, Great Ormond Street.

[SPECIALLY REPORTED AND ABSTRACTED FOR THIS JOURNAL.]

YOU will recognise that this lecture is intended to be more or less popular, and I shall assume that I am addressing many mothers and nurses, as no doubt, in the main, I am. My purpose is to draw upon a fairly wide experience of the subject, and to speak of and recommend to you the foods which I have found to give the best results in the majority of infants.

At the outset I would say that, if possible, children should be fed by the natural method. I feel sure there is no need to labour that. And, fortunately, the natural method is not likely to necessitate much management on your part; but there are one or two points in connection with that part of the question which I want to lay stress upon. The first is the need

---

(a) Abstract of Paper read before the Edinburgh Medico-Chir. Society. Feb. 6, 1907.

(a) A lecture delivered under the auspices of the Incorporated Institute of Hygiene, on Wednesday last, Feb. 6th, 1907.

for regularity in the feeding. This is where mothers often go wrong, and where you will probably be able to put them right. In the first few weeks of life the child should be fed every two hours, certainly during the day, and a couple of feeds should be given in the night. As the child gets older, the interval can be increased, first to 2½ hours, then to 3. Babies being creatures of habit, you will see the great importance of this.

Next, it is very important to have the child regularly weighed. This is your only criterion as to whether the child is thriving, whether it be fed by the breast or artificially. A child which is being fed on the breast should, to be considered satisfactory, gain 6 ozs. in weight per week during the first few months of life. After that, the gain will be slower. If the gain is less than that, you are justified in assuming that there is something wrong.

Next, I would warn mothers against being worried by a little sickness; there is no need to do that if the weight is progressing. I have known cases in which the child has been weaned unnecessarily early because it was sick.

Then, still assuming that the weight is right, it is important to know when to stop the feed One hears a good deal nowadays of the evils of neglecting to feed children at the breast, but enough is not heard of the disadvantages of keeping them at the breast too long. Over-lactation is one of the most potent causes of rickets; some of the worst cases of rickets I have seen were due to that cause. Not only does it produce rickets, but it is complicated by anæmia, sometimes to a profound degree.

With regard to the time for weaning, do not be guided by the popular notion that the appearance of teeth indicates that the infant should be weaned; so that it is assumed the mother should continue putting the child to the breast while it is without teeth. That is not only untrue, but it has done and is doing much harm. Many children who are kept too long at the breast get rickets, and rickets is a very common cause of delayed teething. I think you will not go far wrong if you recommend weaning at the tenth month or thereabouts. And the child which has had ten months breast feeding is more lucky than most.

But what you have chiefly come to hear about are the best methods of artificially feeding infants. I shall not labour the point as to what is the best substitute for human milk, because it is universally agreed that, on the lines of convenience, cow's milk must be the substitute. The great disadvantage of this substitute is the density of the clot which it forms in the stomach. Were it not for that, there would be practically no difficulty with infant feeding. That clot is due to the casein, the essential chemical constituent of cheese. The milk is liquid, but only outside the body. I show you tubes containing human milk and cow's milk combined with digestive fluid, so that you may appreciate the density of the clot in the cow's milk. It requires no knowledge of physiology to understand that the liquid one will be more easily digested than the solid one, because the process of digestion, in its essence, is the reduction of the food to a solution, as only in that form can it be absorbed. The whole purpose of the methods of modifying cow's milk is to overcome this solid clotting. There are various ways in which this may be done, and the diversity of the methods recommended for the feeding of infants depends on the various ways in which the milk is treated.

The first method is dilution. As there is less casein in a given quantity of liquid, the density of the clot will be less. Now, in embarking upon a course of modification for the feeding of infants, you must, to have success, have a definite plan of campaign; there is no use in plunging from one degree of dilution into another, and from one substitute for cow's milk to another, haphazard. I recommend you to never dilute more than half water and half milk. What shall your diluent be? There is a popular prejudice in favour of barley-water; and simply because it is somewhat mucilaginous when it is mixed with the milk, there is a less dense clot. But barley-water, as ordinarily made, contains 1 per cent. of starch, sometimes more, and starch is not a natural ingredient of an infant's diet, and every now and then you will find an infant with whom barley-water will disagree. Certainly there are cases where failure in artificial feeding is due to this cause; the starch passes unaltered into the stomach and intestine, and there undergoes acid fermentation, which in turn causes colic and discomfort. You will do wisely to employ water as the diluent. The nutritive value of barley-water is quite negligible. If you are doubtful about the source from which the water comes, boil it. Adding the same quantity of water as there is milk will bring the amount of casein to nearly what it is in human milk. But it will also bring down the other constituents—the sugar and the fat. You must correct that by adding sugar and cream. To every 6 ozs. of your mixture of water and milk I recommend you to add a couple of drachms of cream and 2 of sugar—I mean the ordinary dairy cream, having 45 per cent. of fat. That, in regard to its constituents, will closely approximate to human milk. Identical with human milk your mixture can never be; there are subtle differences which we cannot make good. If you weigh the child from week to week and find it doing well on this mixture, continue it.

But all infants cannot stand this degree of dilution. There are some, particularly below three months of age, for whom such a mixture is too strong. The tube I show you containing such a liquid shows that it is more flocculent than the human milk. What shall you do in such a case, supposing the child has sickness and vomiting, and there are green, unhealthy motions? I recommend you to see if you can chemically alter the casein without any further dilution. You may be tempted, as people always are, to say, "If half-and-half will not do, we will try two of water to one of milk." I can only say my experience is that that mixture is not satisfactory; at all events, one cannot at all rely upon succeeding with a greater dilution than half-and-half, and it is then very difficult to redress the balance of sugar and fat. In fairly recent times it has been found that with the addition of citrate of soda to milk you can reduce the density of the clot; it is a harmless vegetable salt which, so far as I know, produces no signs that it has been given. One grain of citrate of soda to every ounce of milk (*i.e.*, 2 ozs. of the mixture) will result in there being practically no clot at all, and children who could not digest the half-and-half food will thrive upon this. I show you citrated milk which has been treated with rennet, and you cannot clot that, even if you add rennet and hydrochloric acid. Therefore that will not pass along the bowel in lumps and cause colic. It is better that this citrate of soda should be used under medical supervision; one reason is that the mother may be stupid, and not understand how to do it.

Where the citrate method fails, we must go to the third stage, and that is, condensed milk in some form. I am almost afraid to stand up and recommend the use of condensed milk, because I am very likely to be accused by my professional brethren of preaching heresy. I know the indiscriminate use of unsuitable condensed milk is capable of doing much harm; but good condensed milk, rightly used, is capable of the greatest service in the matter of infant feeding. What do I mean by good condensed milk? In the first place, I mean one which contains all the natural fat, 13 per cent. Secondly, for all practical purposes, I mean the sweetened form. Theoretically, unsweetened forms may be best, but they are not so convenient as the sweetened because they do not keep long after the tin has been opened. There are at least four brands of sweetened condensed milk on the market. How shall you dilute it? I advise you to disregard all the directions on the tin, because they are misleading. Many of the failures in the use of them for infants are due to the makers' directions—they do not do themselves justice. Use it in the proportion of a drachm (an ordinary medium teaspoonful) to 3 ozs. of water. That, as regards the important constituent casein, is almost right—perhaps a little below a good sample of human milk. Where it does come short is in fat. But that is easily remedied by adding a teaspoonful of cream to every 3 ozs. of water. That is better than the half-and-half cow's milk and water, because it contains less casein. In the process of condensing the milk the casein seems to undergo some change which makes it more difficult to clot. You could not form it into junkets if you were to try. You will see, by the tube I shall show you afterwards, that it forms a very flocculent curd when mixed with digestive fluid, very different from that of pure cow's milk. In young infants condensed milk so used will give quite satisfactory results, and if people advise you never to use condensed milk, pay no heed to them. They are people who have never used it in the proper way. Do not continue this beyond the fourth month, or you are very liable to have rickets produced, and there are very few children of that age who cannot digest the half-and-half cow's milk and water. One gets to know by experience—almost by merely looking at a child—whether it is likely to be able to digest a half-and-half mixture. Remember that by continuing a milk or food which does not suit a child and gives it indigestion, you are apt to have difficulties during the rest of its infancy, even after the proper food for it has been found. If a child looks small and puny, and seems likely to have bad digestion, not having got on well with human milk, begin your plan of campaign right away with condensed milk in this form.

Assuming condensed milk does not suit, or that it is not available, what should you do? I think dried, desiccated milk will, in the future, have a great use, though I do not think it is yet in the region of practical politics. You may regard it as condensed milk carried a stage further, preserving all the properties of the milk, so that when dissolved in water it will reproduce condensed milk; so that when you add rennet it does not clot. I have known young infants able to take more desiccated milk than would be represented by ordinary cow's milk, dissolved in water, and digest it well. Desiccated milk cannot be said to be yet generally available, but I think it will be in great vogue in the future. It is comparatively sterile, and is an easily managed substitute for ordinary cow's milk.

If even condensed milk fails, you can try milk which has been peptonised. But a baby which is bad enough to be fed on peptonised milk is bad enough to be under the care of a doctor. So, although I have put it down as the last card to play in your campaign, it is one which you are not likely to use often on your own responsibility. I mean peptonising by one of the preparations which are on the market. After peptonising the milk, you can dilute it down to half-and-half, and you will find many children will thrive on this who cannot digest any other form. This does not clot. I show you some peptonised milk which has been pancreatised. The whole object of pancreatising is to do the work of the child's stomach for it.

Suppose that, after trying all these methods, you still have difficulty; that the child still fails to gain weight, and has unhealthy motions, what shall you conclude? I think you may conclude that you are dealing with one of those children who cannot digest cow's milk at all, no matter how you treat it. And in such a case as that, it is very difficult to know what to do. But I need not trouble you with these cases, because they should always be placed under the care of some responsible medical man. And they form a very small minority indeed of the total cases.

Next I want to say a few words about the technique of the feeding—that is, as to how you are to give those foods. I have given you a table of times of feeds and the approximate quantities. These are only approximate. There are people of an inquiring turn of mind who want to know exactly how many ounces each feed should consist of, but I think that should be left to the baby. You cannot tell how many ounces and grains any person in this room may want to eat at dinner. The appetites of grown-up persons vary, and so do those of babies, and there is no good in aiming at scientific accuracy in this matter. Still, there are some fussy mothers who think you should be able to tell them that.

With regard to the feeding bottle, I am glad to say that correct views are beginning to prevail on this matter. The tube bottle is rapidly being discredited, and I hope you will do your best to get the screw bottle equally discredited, as that does quite as much harm. Stale milk and added harmful matter gets harboured in the screw, just as in the tube, and both are not likely to be absolutely cleansed between each feed. The best is the plain oval bottle with a rubber teat in the top which you can turn outside in. All these elaborate arrangements to let in air and prevent a vacuum are not necessary. The human breast is not equipped with air-holes, and I do not see why feeding-bottles should be, either. You must see that the hole in the top of the bottle is big enough. I have known children nearly starved through neglect of this precaution. If when you invert the bottle of milk the liquid comes away at the rate of one drop per second, the child will feed easily enough. If it comes less quickly, the child may starve, or at least becomes exhausted; if it comes quicker, the infant may be over-fed. The "leech-bite" bottles are not regulated carefully enough in this regard.

Lastly, I have something to say about patent and proprietary foods. I have handed round a sheet showing the composition of most of the patent foods on the market. It is not quite up-to-date. I do not abuse patent foods all round; they undoubtedly have their place, and fill a useful purpose. But it is very rare for a child which cannot thrive on food prepared in one of the ways I have explained to do so on a patent food. Group I. in this table are to be used instead of human milk. Group II. have been starchy to begin with, but that starch has been converted into sugar. Group III. consists of foods which contain starch.

It is seldom you find a child able to take the foods in Group I. which could not digest condensed, or citrated, or peptonised milk. Sometimes one of the foods may happen to suit, possible because the child likes it. The foods in Group II. are useful when the child is about six months old, and when it has got a tooth or two, but cannot digest much starch. These foods should be only supplementary to the milk. With regard to the foods in Group III., one should discourage the use of them until the child has got teeth. Most of them are expensive, and can be substituted by simpler means—wheat flour, oat flour, boiled crusts.

Weaning should be carried out about the tenth month, whether the feeding has been by breast or by bottle. If you keep the child on milk too long, you will have a difficulty in getting it to take solid food at all. I have known mothers defer feeding until the second year. After weaning, commence feeding by means of something with a spout, and follow with a spoon. Do not give starchy foods until the child has got a few teeth through; let them be subsidiary to cow's milk, and use ordinary domestic foods in preference to patent preparations.

There are many different ways of feeding children, and those I have given are not all of them; but they are methods which, in the main, you can apply; they are not time-consuming, or troublesome, or expensive, and therefore they are peculiarly suitable to the class among whom nurses have to do their work.

TREATMENT OF PERITONITIS.

BY H. W. CARSON, F.R.C.S.ENG.,

Surgeon to the Tottenham Hospital.

DURING recent years many investigators have been engaged on the problem of the resistance of the individual to disease, and it is now recognised that in disease the fight is between the specific organism and its toxins and the leucocytes in the blood, and that the incidence of infection is followed by an increase in the number of leucocytes (hyperleucocytosis). Issaeff, Loewry and Richter, Jakob and Salieri were pioneers of this work, and Salieri succeeded in causing hyperleucocytosis by injecting sterilised saline solution int the peritoneal cavity. Hahn showed that in hyperleucocytosis the blood had a higher bactericidal value. Mikulicz and Miyaké, by injecting saline solution and nucleic acid into the peritoneal cavity, succeeded in increasing the resisting power of the peritoneum to infection 16-20 times. Dudgeon and Sargent maintain that in peritonitis the first organism to appear is the staphylococcus albus, and that this organism, which is of low virulence, causes a fluid exudate containing innumerable phagocytic cells, which is essentially protective against the more virulent organisms which may appear later. Not only is the white staphylococcus the first to appear, but it is also the last to disappear, and Dudgeon and Sargent suggest that this may account for the well-known fact that in appendicitis the first attack is the most severe, subsequent attacks being of less severity owing to the persistence of the white staphylococcus. In this connection it may be mentioned that in my report of 100 consecutive appendix operations read at the Toronto meeting of the British Medical Association in August last, I showed that of the 70 acute cases

55, or 78.5 per cent., were first attack cases;
12, or 17 per cent., were second attack cases, and
3, or 4.5 per cent., had had more than two attacks.

Other facts of great importance in connection with the pathology of peritonitis may be briefly summarised:—

1. Muscatello of Turin proved that the diaphragmatic area is chiefly concerned in the absorption of fluid from the peritoneal cavity.
2. Injury to the endothelial coat of the intestines permits of absorption taking place directly into the vascular system, and if the fluid absorbed is pathogenic, toxæmia follows.
3. The virulence of intestinal organisms increases from the jejunum to the ileo-cæcal valve, decreasing again in the large intestine. This virulence is much increased in intestinal obstruction.
4. Organisms escape from the intestine as soon as it becomes inflamed and distended.

I wish to-day to consider the treatment of peritonitis as viewed from the standpoint of recent bacteriological research, to see how far our former methods were justifiable, and in what respects we must remodel our procedures.

It is now generally recognised that the operative treatment of peritonitis is the only course to adopt if the patient is to have a fair chance of recovery, so that we may fairly discuss treatment under the three heads—

1. Pre-operative.
2. Operative.
3. Post-operative.

PRE-OPERATIVE STAGE.

To the practitioner in general practice this is the stage of greatest importance. The most important point of all is the ability to diagnose the condition early. I do not propose to-day to enter upon the question of diagnosis, as time is limited. The diagnosis having been made, the question to be answered is not "How shall I treat it?" but "What can be done previous to operation to improve the patient's chance?" The patient is in great pain and distress, and one's thoughts turn naturally to some form of anodyne, and the points for and against the administration of morphia must be considered. Both clinically and bacteriologically many arguments can be adduced against this practice. From a clinical standpoint it is, I suppose, a truism that morphia tends, as the well-known phrase runs, to "mask symptoms." Every surgeon who has had experience in abdominal surgery will subscribe to this statement, and it has seemed to me that morphia has a special power in those cases which, bacteriologically considered, are not of extreme virulence. I refer more particularly to cases of perforative gastric ulcer. The administration of morphia may give an elusive appearance of wellbeing to these cases, which may lead to the deferring of the operation, and we know that in these milder forms of infection an early operation is followed by a very flattering measure of success. But this is not the only argument against morphia administration. It has been proved by the researches of Dudgeon and Ross that morphia has a definite action in *inhibiting leucocytosis*, that is to say, it takes from the patient his only weapon of defence. Considering that our whole aim in the treatment of peritonitis is to encourage leucocytosis, one recognises how fatal the use of this drug may be, and how directly it runs counter to the rest of our treatment. Next, morphia tends very definitely to *reduce intestinal peristalsis*, and this leads to distension of the gut and stasis of the intestinal contents. I have mentioned above that the intestinal organisms escaped from the intestines only when they were distended, and that in stasis of the intestinal contents the virulence of the organisms was directly increased, so that one sees that the administration of morphia increases the virulence of the infection and aids its dissemination. The dissemination of infection is also aided by the fact that owing to the relief of pain which follows on morphinism, the rigidity of the abdominal walls is reduced, and the diaphragm can move more easily in respiration. This tends to cause distribution of the infecting material, though our aim is of course to limit it to the primary area. The great argument in favour of morphia is that it relieves shock and saves the patient from the depression of pain. This is true, and in some cases of virulent infection it may have a definite value; but as a routine treatment I most unhesitatingly condemn it. It has been said that it is not the simple injection of morphia that is so dangerous, but the continuance of treatment by morphia, and that if a single injection does not relieve pain, or prevent its early recurrence, the case is one for operation. I must say I have a greater belief in the diagnostic powers of my fellow practitioners than to think that it is necessary to use morphia in order to estimate the need for a surgical operation. It has been urged that if the diagnosis is made and operation decided upon, morphia may be safely and advantageously administered. That certainly overcomes the difficulty of the "masked symptoms," but it does not answer the other objections I have raised, nor does it alter the fact that many patients, morphinised before operation, show evidence of definite motor paralysis of the intestines after operation, and I have many times had the greatest difficulty in counteracting this. To sum up, then, I would urge that although in exceptional cases morphia may be of value, its routine use is to be strongly condemned. What, then, shall be done before operation? I am convinced that of all methods the best is the administration of a turpentine enema. If this results in the passage of flatus, the relief to the patient will be immediate, and a step will have been taken to counter the intestinal distension which so definitely favours the passage of the intestinal organisms through the wall. The administration of small doses of calomel should, I think, be deferred until the nature of the lesion is definitely assured. As I shall mention presently, it is a very valuable post-operative measure. Further, I should recommend that the patient should be placed in such a position that the exudation will tend to gravitate towards the pelvis. This posture method, to which I shall refer in greater detail under Post-operative treatment, is adopted in order to prevent soiling of the diaphragmatic area, and thus to delay the absorption of the bacterial toxins. Finally, relief to pain may be obtained by the local application of heat—e.g., turpentine stupes—care being taken to avoid injury to the skin.

OPERATIVE MEASURES.

I have pointed out the danger of direct vascular absorption if the endothelial coat of the intestines is injured. This is the keynote of all operative measures. To avoid injury to the endothelium we must, above all, do our work quickly and gently. We must avoid rough handling, we must avoid antiseptics, we must prevent the peritoneal coat becoming dry, we must protect the peritoneum from soiling with the intestinal contents, and we must give up heroic measures of evisceration, extensive lavage, scrubbing with gauze, and so on. The researches of Crile show that the amount of shock is directly proportionate to the amount of traumatism. He showed that exposure of the intestines to air, manipulation, and sponging caused a fall in blood-pressure and an increase in the pulse-rate. He showed that flushing the abdomen caused a lowering in the blood-pressure, and you will find that anæsthetists will readily agree that the pulse is perceptibly weakened by this treatment. An important fact is noted by Crile, that most change in blood pressure occurred in operations near the diaphragm, and on all sides we find reasons for looking upon this region as the most important area within the abdomen. In this connection it is interesting to note that Crile reported that all operations on the female generative organs—hysterectomy, oöphorectomy, even perineorraphy—were associated with a definite *rise* of blood-pressure.

Our first duty is to the primary seat of infection. It is our object to so treat this that further infection from the spot may be impossible. That is, a perforated ulcer must be sutured, a localised abscess drained; a gangrenous appendix or portion of intestine removed, and so on. All these operations must be done with the minimum of manipulation, the greatest care being taken to avoid breaking down adhesions or in any way disseminating infection. If the abscess is circumscribed while the general peritoneal cavity is not shut off, as in cases of subcæcal appendix suppuration, the general cavity must be carefully walled off with swabs before the abscess is opened, and these swabs may be left in position for a day or two if necessary. If the peritoneum is widely infected, the question of flushing arises. The object of flushing is of course to free the peritoneum from infective organisms and their toxins. Dudgeon and Sargent have by their researches proved that much of the exudate is protective in character, and that in the earlier stages the virulent organisms, such as bacillus coli, have not appeared universally. With this in mind, it is obvious that if we thoroughly flush out the abdomen, while we cannot hope to rid the endothelium entirely of the infection, we run a practically assured risk of washing out the protective staphylococcus albus exudation, and in addition we may infect with virulent organisms parts of the peritoneal cavity which were hitherto free. Also, for thorough flushing, evisceration is necessary, and I have stated above how evisceration and flushing tend to lower blood-pressure. Local flushing is a different matter, and though this is difficult in the appendix region, it is capable of thorough application in the pelvis. And here I would remind you that antiseptics should not be used at all in the abdomen. Their effect is to injure materially the endothelium, and to interfere with the ability of the phagocytes to do battle with the infecting material. Experiments have proved that the untreated peritoneum is capable of neutralising the toxins of a much larger dose of bacillus coli than it can do if previously prepared by the injection of antiseptics. There is no doubt that much of the success that has of late years attended upon abdominal surgery has been due to the wide adoption of aseptic for antiseptic measures. At the two extremes of peritoneal infection it may be permissible to flush. These are, on the one hand, the very severe types of streptococcal peritonitis where infection is practically universal, and, on the other, the mild type found in hæmorrhage, or some cases of perforated gastric ulcer. In the former there is no risk of infecting a previously free area, and in the latter the virulence of the infection is so slight that the danger is reduced to a minimum. I do not think, however, that much is gained in either case, as in streptococcal invasions, flushing does not lower the mortality, and the mild cases do very well indeed with simple drainage. Murphy, of Chicago, indeed, stated at Toronto that in his last 36 cases of general peritonitis he had had several streptococcal cases, and although he did not flush in any case, he had only lost one of the 36 cases, and in that case death occurred six days after operation of double pneumonia, the peritonitis having quite cleared up. As an illustration of the dangers of flushing, it may be stated that in the five years 1899-1903 119 cases of appendicitis with diffuse peritonitis were operated upon in St. Thomas's Hospital; 100 of these were flushed out with large quantities of normal saline, and of these 80 died. The remaining 19 were treated locally by sponging and drainage, and of these 10 died (Dudgeon and Sargent). So that in this instance the mortality attending on flushing as compared with local drainage is 80 against 47, and allowing for the chance that many of the most severe cases are included in the first list, the difference in the mortality is striking. Drainage should be resorted to in all cases where infection with the bacillus coli or more virulent organisms is feared. In mild infections with the staphylococcus albus only, *e.g.*, hæmorrhage cases, drainage is not necessary, for we know that the staphylococcus albus is not capable unaided of causing a fatal peritonitis. The drain must be put in one of three places—either in the pelvis or the loins. A tube placed centrally to drain the small intestine area is useless. In the event of Fowler's position being adopted, drainage of the loin pockets need not be provided, as the contents of the lateral parts of the abdomen will drain by gravitation into the pelvis. We may then sum up our operative procedures as follows:—

1. Elimination of the primary cause.
2. Avoidance of manipulation, breaking down adhesions, flushing, etc.
3. Continuous drainage.

POST-OPERATIVE.

Our aim in the after-treatment of peritonitis is to promote leucocytosis, prevent the further infection of the peritoneum, and eliminate the toxic products of the infecting organisms before they can become absorbed into the circulation.

In the present state of our knowledge it is not possible to promote leucocytosis by the administration of any serum. The organism which it is most necessary to combat is the bacillus coli, and at the present time no serum valent against the varieties of the colon bacillus has been manufactured. With respect to other forms of infection, the streptococcus is so virulent that polyvalent antistreptococcic serum is of little avail, though its use is indicated if the streptococcus is isolated from the exudate. The other forms are not of sufficient virulence to require other than the ordinary treatment. But there is a method of causing hyperleucocytosis which is readily available. This consists in administering saline solution by the rectum or subcutaneously. In giving the rectal injection, the buttocks are raised, a multiperforated tube is passed just within the internal sphincter, and through it is passed, in a continuous stream from an irrigator, one or two pints of saline solution. This should be passed so slowly that one pint takes half an hour, and no fluid should return. Practically the fluid is absorbed as it is injected. The irrigator should be attached to a stand not more than 4-6 inches above the pelvic floor, and the nozzle can be strapped to the patient's thigh. This is a most valuable method of treatment, and it should always be resorted to even in less serious cases if the discharge tends to cease too soon. In my opinion, if in, for intance, a case of appendix abscess, discharge ceases or becomes much reduced in the first few days, it means that leucocytosis is low, that the patient is not making a sufficient opposition to the enemy, and unless steps are taken to overcome this, the result will be doubtful. The best method is this I have mentioned of rectal irrigation.

To *prevent further infection* it is necessary to prevent intestinal distension, and to promote peristalsis, and the passage of the contents along the intestinal tract. As I have told you, the organisms escape from the bowel during distension, and if stasis occurs the virulence of the organisms becomes much increased. With this in view, morphia is absolutely forbidden, no matter what the apparent necessity, and some such drug as aspirin used to relieve pain. The pain is, however, generally due to distension, and this must be combated by enemata preferably containing turpentine. Another method, and one of great value, is to administer by the mouth repeated small doses of calomel. These doses may be as small as one-sixth of a grain, and should not exceed one grain. They may be given every hour till some relief is obtained. In some cases they may be associated with a saline or potassium tartrate.

To eliminate the toxic products we must rely upon drainage, and knowing that the great area for absorption is the diaphragmatic surface, it is well to place the patient in such a position that the fluids tend to gravitate away from the diaphragm. This is obtained by placing the patient in what is known as "Fowler's position." The head of the bed is raised about 2 ft., and the patient supported by a pillow slung beneath the thighs, in a semi-sitting position. This position is always associated with a pelvic drain. The patient must be carefully watched to see that the raising of the head does not cause faintness. Now a final word as to the technique of our operation. The surgeon should bear in mind the necessity of protecting as far as he can the small intestine from the septic focus in the pelvis (for this, owing to gravitation, becomes septic in the majority of cases). He must recognise that if the small intestine is allowed to bathe in a collection of pelvic pus, he runs a very great risk of having to deal with an obstruction by kinking during the convalescence. To prevent this, he must pack the sigmoid or the rectum into the floor of the pelvis, and draw down the omentum and tuck it in beneath the uterus or bladder, so as to exclude altogether the small intestine from the pelvic area. In spite of all care, ileus may however occur, and it is necessary that it should be at once recognised if the patient's life is to be saved. It may be difficult to differentiate between true ileus and intestinal paresis from distension. In many points they resemble each other, but in my experience one of the most reliable points in diagnosis is that ileus is preceded by severe pain; vomiting, rise of pulse-rate, and inability to pass flatus supervening rapidly. In intestinal paresis the onset is generally much earlier after operation; there is no more pain than would be caused by the feeling of abdominal tightness, vomiting is not so urgent, and unless toxæmia is marked, the pulse rate is not so obviously increased. It will always be found that the point of kinking is in the last 6 in. of the ileum, and if the abdomen is promptly opened, the condition can frequently be satisfactorily dealt with.

OPERATING THEATRES.

ROYAL EAR HOSPITAL.

INFLUENZAL MASTOIDITIS, SCHWARTZE OPERATION.—Mr. MACLEOD YEARSLEY operated on a woman, æt. 43, who had been admitted with the following history: Five weeks previously she had been attacked by influenza; one week later severe pain with discharge occurred in the right ear; the discharge was more serous than purulent, and usually contained blood. Under treatment by Dr. Cardinall, of Sidcup, the discharge ceased, but pain of a severe neuralgic character, radiating over right side of the head and down the neck, remained, together with tenderness over the lower part of the mastoid process. On examination, the osseous meatus was found to be much congested, especially in its superior posterior part. Shrapnell's membrane, together with the handle of the malleus and the posterior superior quadrant of the membrana tensa, was injected; in the latter region was the scar of a recent perforation. Tenderness over the lower part of the mastoid process was marked, especially about the tip. The patient appeared ill; her temperature was 96.8°, but there was no nystagmus, vertigo, or other serious symptom, and her deafness was not very marked. At the operation, the mastoid was found to be of the pneumatic variety, and each cell was occupied by granulation tissue, the bony walls between them being soft and crumbly. The antrum contained no pus, but there was a fairly large granulation in the region of the aditus. The whole mastoid was cleared out and, on reaching the tip, pus welled out, verifying the diagnosis which had been made of an abscess in the tip cell. The meatus was thoroughly purified, and an incision made in the posterior segment of the membrane. The mastoid cavity was packed and the wound sutured in its upper two-thirds. Mr. Yearsley said that this case was very interesting as illustrating several important points in influenzal mastoiditis. Acute inflammations of the middle ear occurring in the course of influenza might, he pointed out, take one of three forms: (1) A distinctive type of hæmorrhagic otitis with a discharge often scanty and for the most part sero-sanguinolent (this apparently affected the patient just operated upon); (2) a primary mastoiditis due apparently to direct infection rather than to extension; (3) a rapid caries or necrosis of the ossicles or mastoid. A prominent feature of influenzal mastoid disease, present in this case, he remarked, was severe radiating pain of a neuralgic character. He had more than once seen cases similar to the present one in which serious mastoid disease was present with such equivocal symptoms as to almost merit the term latent, the mastoid complication existing after the middle-ear condition had practically cleared up. Another point prominently illustrated by this case, he thought, was the variety of mastoid specially attacked by influenza. As long ago as 1892, Politzer pointed out that this form was the pneumatic, in which there were numerous cells communicating with each other and with the antrum by very small openings. These tiny communications become closed by inflammatory swelling, a collection of pent-up pus resulting. These abscesses were to be found in the middle or inferior segment of the vertical portion of the mastoid, the tip cell being a common locality. Looking at the history of the case, and especially at the time which had elapsed (four weeks) since the onset of the aural symptoms, it appeared likely that the mastoid condition and the tympanic inflammation were part and parcel of one process rather than that the former was the direct result of the latter. One could not bear in mind too prominently, he considered, the fact that serious mastoid trouble might occur in influenzal cases without giving by their symptoms adequate indication of their extent and gravity. It behoved, therefore that surgeons should lose no time in temporising with such cases, but should act promptly.

TRANSACTIONS OF SOCIETIES.

CLINICAL SOCIETY OF LONDON.

MEETING HELD FRIDAY, FEBRUARY 8TH, 1907.

The President, Mr. CLUTTON, in the Chair.

DR. FRANCIS HAWKINS (Reading) read notes of a case of

TYPHOID COMPLICATED BY PERICARDITIS AND HÆMORRHAGIC PLEURISY.

The patient was a girl, æt. 20, whose illness commenced with sore throat and a feeling of stiffness in the legs. Five days later she had a shivering fit, followed by diarrhœa. During the course of the illness no typhoid spots appeared, but the abdomen was distended and the bowels moved from twice to seven times daily. Widal's reaction was positive. Early in the third week she expectorated blood, and two days later the expectoration was typically rusty. The physical signs gave evidence of consolidation of the left base. Pericardial friction was heard during the fifth week, when the patient's condition became critical. The respirations were 42, the pulse 128. Paracentesis was performed, and 14½ ounces of hæmorrhagic fluid withdrawn. After paracentesis, the patient improved, but the temperature did not become normal till the seventh week. A systolic murmur was heard at the apex in the third week. Dr. Hawkins remarked on the great rarity of these complications in typhoid fever.

Dr. **WM. EWART** inquired as to details of the treatment employed.

Dr. **DE HAVILLAND HALL** suggested that the phenomena might have been due to a superadded rheumatic infection.

Dr. **HALE WHITE** suggested that the whole disease might have been one of pneumococcal infection. There was an assemblage of features, each of which individually was extremely rare in typhoid fever. The temperature chart was very unlike what is ever seen in typhoid, and there was no other clinical indication of the disease. He inquired as to the dilution of the Widal test and the frequency with which it had been done.

Dr. **FORSYTH**, in view of the origin of the complaint—sore throat and joint pains—asked what was the effect of salicylates. Was there any history of previous typhoid fever.

Dr. **HAWKINS**, in reply, said that he had treated the case with hydrochloric acid. He found this the best antiseptic to use as a routine measure in typhoid cases. The fever had fallen for a couple of days when salicylates were given, but had risen again. As to the Widal's reaction, it had been tested only once, the blood having been sent to a Clinical Research laboratory in London. As seven years had elapsed in the meantime, he could not recall the dilution employed, and there was no note of it. The patient might have had typhoid fever previously.

Mr. **JOHN R. LUNN** and Dr. **GORDON HOLMES** gave an account of the clinical and *post-mortem* notes of a case of

GENERAL PARALYSIS

in a boy, æt. 16. A clinical description of the case was presented when the patient was shown at a clinical meeting of this Society, January 26th, 1906. The patient remained in the same condition until February 15th, 1906, when he had an unconscious fit, which was accompanied by more weakness of his left arm and leg. In August, 1906, it was noted he had right facial paralysis, and a spasmodic spastic condition of the left arm and leg with incontinence of urine. On September 15th, he had another fit with conjugate deviation of his eyes to the left and increased knee-jerks. He died September 13th, 1906.

Post-mortem Notes.—The skull was opened from behind and the brain and cord removed. A recent blood clot of about eight ounces was apparently situated between the dura mater and arachnoid membrane, and had compressed the brain considerably on the left side. No rupture of any sinus could be found. After the removal of the brain, blood could be squeezed out of the cerebral veins in two places, one over the left frontal lobe, the other over the left occipital. This, it was thought, might possibly be the source of the hæmorrhage. No other lesions were found in the body.

Dr. **GORDON HOLMES**, in demonstrating on the screen a series of microphotographs, said the most marked changes found were as follows. :—There were striking changes in the blood-vessels throughout the brain, large numbers of plasma cells being evident in their sheaths. There was syphilitic endarteritis in some vessels of the lumbar cord. The tangential fibres of the cortex were greatly diminished. There was advanced granular ependymitis extending even to the fourth ventricle. The meninges were not thickened. The changes were quite pathognomonic of general paralysis of the insane, and thus fully confirmed the clinical diagnosis. He remarked on a curious tremor of the left hand, that the boy had had at times lasting for twenty minutes. He had previously seen a similar tremor only twice ; it indicated irritation of the arm area.

Dr. **WM. EWART** inquired as to the pathogeny of the changes.

Dr. **PARKES WEBER** asked about the microscopic appearances of the ependyma.

Dr. **GORDON HOLMES**, in reply, said that the changes indicated a chronic inflammation due to blood toxins. The ependyma showed interruption of its lining cells, and increase in the glia. It was not very vascular and the walls of the vessels were hyaline.

Dr. **MORLEY FLETCHER** and Mr. **BETHAM ROBINSON** read a paper on a case of

IDIOPATHIC DILATATION OF THE RECTUM AND COLON AS FAR AS THE HEPATIC FLEXURE.

A boy, æt. 12, admitted into the East London Hospital for Children on November 15th, 1904. There was a history that he had always had a " large belly," and been rather constipated, and that for the last fortnight there had been a great increase in the size of the belly, with more marked constipation, but no vomiting or passage of blood per rectum. On admission the abdomen was tense, with distended surface veins. The percussion note was resonant all over, and in the knee-elbow position a thrill was obtained over a small area round the navel. On palpation irregular masses were felt in the region of the transverse colon. On rectal examination the tone of the sphincters was normal, but the rectum was very dilated. While under observation for a fortnight there was no response to aperient medicines and only poor results from enemata. Abdominal section was done on November 29th, and extreme dilatation of the rectum was found, with enlargement of the colon as far as the hepatic flexure. The dilated bowel contained many pounds of soft dark fæcal matter which was squeezed out of the anus by gradual pressure on the gut from within. There was considerable hypertrophy of the bowel wall. No large or hard glands were felt in the mesentery ; there were no signs of peritonitis, nor any abnormal band. After this thorough emptying of the bowels, the patient's progress was most satisfactory. He was kept under observation, and in March last it was noted that he appeared to be perfectly well, his abdomen was quite natural and free from any abnormal distension. The bowels acted regularly and naturally without medicine. Rectal examination showed some ballooning of the gut. He was shown at a clinical meeting of the Society on April 23rd, 1905. He continued in good health until the evening of July 2nd, when he had abdominal pain without any distension ; there was diarrhœa which continued for several hours. Next day he was admitted into hospital in a comatose state, and shortly after died. The *post-mortem* corroborated the condition of bowels seen at the operation, only much less dilated. The lining membrane of the bowel was healthy, and no cause for the dilatation could be found. Most important points in the case were (*a*) the great improvement which followed simple emptying of the distended bowel, followed by careful dieting and regulation of the bowels ; (*b*) the sudden termination with coma, which suggested the ingestion of some toxic substance by mouth.

Dr. **A. E. GARROD** referred to two similar patients in his practice in whom repeated attacks of tetany occurred, indicating absorption of toxins. These were relieved by enemata.

Mr. **MAKINS** discussed the problem of treatment. He thought that anastomosis at the base of the dilatation was unjustifiable on account of the tendency for a new dilated loop to form. He instanced three personal cases in which this had occurred ; they were all in elderly people.

Mr. **CLUTTON** advised colotomy and a prolonged period of thorough drainage before attempting any of the more extensive operations.

Mr. **JOHN MALCOLM** spoke of the possibility after anastomosis of the hypertrophied lower portion of the gut forcing the fæces backwards into the dilated part as well as onwards.

Dr. **HALE WHITE** thought that if this mechanism were at work, then dilatation should be a much commoner condition than it really is. He commented on the extraordinary rarity of such cases ending in coma.

Dr. **DAVID FORSYTH** thought that Mr. Malcolm's view was supported by looking on the continuity of the intestine after such operations as having been restored anatomically, but not physiologically. The wave of peristalsis must be impeded by the scar tissue.

Dr. **PARKES WEBER** inquired as to evidences in the urine, such as the presence of indican, of absorption from the dilated gut. These were to be found as a rule more in cases of acute diarrhœa than in those of severe constipation.

Dr. H. A. **CALEY** thought that the present case might have been due originally to fæcal obstruction.

Mr. **MAYO ROBSON** remarked that the sphincter muscle in these cases sometimes showed pathological changes, particularly fibrosis.

Dr. **MORLEY FLETCHER**, in reply, said that the sphincter muscle was quite normal in the present case. He remarked that the circumference of the gut had diminished by five inches between the time of operation and that of the autopsy.

ROYAL ACADEMY OF MEDICINE IN IRELAND.

SECTION OF MEDICINE.

MEETING HELD FRIDAY, JANUARY 18TH, 1907.

The President, J. M. **REDMOND**, in the Chair.

THE TREATMENT OF GASTRIC ULCER.

DR. LITTLE briefly referred to the morbid anatomy, the causation, and the symptoms of gastric ulcer, and dwelt on the paramount importance of rest in bed, on the value of fluid diet, and of various drugs for the relief of pain, the arrest of hæmorrhage, and the cure of persistent vomiting, and on the objections to uniting the stomach to the jejunum, and urged the attempt to cure the ulcer by medical means, though if it failed he readily invoked surgical assistance.

Sir **CHARLES BALL** discussed briefly the cause of non-malignant gastric ulcer, disowning any belief in the self-digestion theory, and laying great stress on the mechanical effect of food passing over an injured spot in keeping an ulcer from healing. He then gave his experiences of some 40 cases of gastro-enterostomy, pointing out the success of this treatment in non-malignant ulceration.

Dr. **LINDSAY** (Belfast) said he thought the disease must be decidedly common in the North of Ireland, as he found from the reports of the Royal Victoria Hospital that they had 110 cases in 1905, 70 the previous year, and 69 the year before that. As regards the conditions that would warrant the diagnosis of ulcer he was hardly prepared to admit that they must wait for hæmorrhage. He was inclined rather to say that in any young woman, especially one who was debilitated or anæmic, if she had much pain after food, occasional vomiting, and a small area of tenderness in the epigastrium, the evidence for ulcer was fairly satisfactory. Most cases of this kind had ulcer as their basis: There were, of course, differences of degree. Gastralgia should be diagnosed with caution, and only when ulcer could be fairly excluded. A period of complete rest was very important, with a restricted diet. They should also employ alkalies, and probably bismuth, as well as various remedies for the relief of pain, such as hot fomentations, poultices, flying blisters, opium and morphia. Such was a general idea of treatment, but there were differences of opinion and practice in regard to details. How long should strict rest be enforced? For an ordinary case he suggested a period of three weeks as an average, but that period might with advantage often be extended. As regards diet, he agreed with Dr. Little that they must not think only of the ulcer; they must bear in mind the constitutional condition of the patients, and the necessity for putting them in a favourable condition for promoting healing of the ulcer. In cases of recent hæmorrhage he put the patient for a short time on nutrient injections. This, however, he only regarded as a temporary expedient. It was not usually well tolerated for a period of more than a week or ten days. In other cases he had been in the habit of keeping the patient for three weeks at least on milk and strained soups or beef juices. In recent times there had been a considerable revolt in Germany against too strict a dietary. Leube allowed rice, sago, soft-boiled or raw eggs, calves' brains, and even boiled chicken and pigeon at the end of ten days, and scraped raw meat by the seventeenth day. Lenhartz allowed raw eggs with a little wine, milk freely, and sugar even from the first day. Senator allowed throughout gelatine, jelly, cream, almond solution, and iced butter. The general drift of such advice was to allow a considerable amount of liberty even from a very early stage, and even where hæmorrhage had been present. These recommendations had one point in common—the avoidance of the evils of under-nourishment. A diet rich in albumen had the further advantage that it tended to check hyper-acidity. Probably in these islands they had gone to the other side, and leaned rather to the advocacy of a dietary too exclusively designed for sparing the stomach. In view of German advocacy, he had lately given himself more liberty, though not to the extent of the quotations which he had made, and he had not yet seen a case where such liberty had led to mischief. He had allowed whipped egg, animal jellies, and butter and cream, from an early stage of these cases. There was much room for discretion in such matters, and the amount of pain was an important guide. He had already mentioned the use of alkalines and bismuth; he was not inclined to think very highly of nitrate of silver, nor was he inclined to favour the washing out of the stomach. He attached great weight to care during convalescence; much physical rest and cautious return to a generous dietary were points of great importance. In the treatment of hæmorrhage he recommended absolute rest, an ice-bag to epigastrium, nutrient enemata, but he felt doubtful as to the ordinary astringents. The symptoms of partial pyloric obstruction might be mitigated by a carefully regulated diet and occasional lavage. In his experience recovery in a good many cases was not complete, more or less pain and discomfort remaining after food. It was probable that in such cases they were dealing with a partially healed ulcer, or that adhesions had taken place. A second course of medical treatment might be undertaken, but he thought the time had then arrived for invoking the aid of surgery. In relapsing cases particularly he recommended the consideration of whether operative measures should not be resorted to. They might be able in that discussion to draw the line more clearly between the place of the physician and the surgeon in such cases. Nothing was more desirable than complete harmony and co-operation between both sides of the profession. The physician should recognise that the intervention of surgery in that field of practice had been a great boon to suffering humanity; he should be careful not to postpone too long his appeal for assistance to a surgical colleague, and he should seek that assistance in most, if not all, relapsing and chronic cases. On the other hand, the surgeon should recognise that his assistance was only required in a minority of such cases; that a full and even patient trial of medical measures was always the first duty; he should be chary of mere exploratory operations, which were likely to redound neither to the credit of surgery nor the advantage of the patient, but in such cases as those described by Sir Charles Ball, where the indications were fairly clear, he should intervene with promptitude and operate with boldness. Such intervention would undoubtedly lead to the best results.

Mr. **MITCHELL** (Belfast) said gastric ulcer is a much more serious disease than is generally recognised. The mortality is very difficult to estimate. Mr. Keeley puts it at 25 per cent., and states that at least 20 per cent. of chronic cases develop phthisis, while not less than 5 per cent. perforate. If these figures are even approximately correct, we are bound to consider much more frequently than we have yet done the question of operative treatment. Do not let us make any mistake; an abdominal operation of this kind is a serious thing to propose, and serious to carry out; but in competent hands the risk should not exceed 5 per cent.—in other words, it is no greater than the danger of perforation, in which the patient already stands. "Exploratory" operation is, in my opinion, an unscientific proceeding. There should always be some definite diagnosis, and operations should be undertaken with a deliberate object in view. In other words, we set out intending to perform posterior gastro-jejunostomy, but owing to various complications this procedure may require to be modified. This is very different, however, from *opening the abdomen to see whether it ought to have been opened*, for that is really what an exploratory operation generally means. Not at all infrequently there is little pathological to be seen in the stomach; but a few silvery adhesions here or there, or some enlarged glands in the omentum, will be found on careful examination, indicating damage to the mucous membrane. Tubercular disease of the stomach is, I think, commoner than is generally believed. I have had three undoubted cases in 48 consecutive operations. They all benefited decidedly, but progress is slower than in ordinary ulcer. As to cure, my impression is that a properly performed gastro-jejunostomy may pretty confidently be relied upon to cure 90 per cent. of cases, and those in which failure occurs will be found to have some other ailment militating against success. I have not yet had occasion to operate for the arrest of acute hæmorrhage, but do not feel inclined to do so. For recurrent hæmorrhage gastro-jejunostomy is the treatment. Operation is not to be recommended for all cases of ulcer, but unquestionably it should be resorted to more frequently than it has been. After a fair trial of thorough medicinal and dietetic treatment without satisfactory results, operation should at least be considered before the health of the sufferer is undermined, and the stomach so deformed or adherent as to require some elaborate and dangerous surgical procedure. The duration of treatment is a point of some importance. One month may be regarded a full time for complete cure by operation. Under medical treatment a patient is fortunate if at the end of a month she is timidly attempting an average diet.

Dr. Cox said his conviction and experience had been that the majority of cases had a tubercular history. Whatever the subsequent development had been, they were primarily tubercular as regards causation. From that point of view he regarded Dr. Lindsay's remarks as regards the question of generous diet as very important. The ulcer must not be regarded primarily as a local condition, but as an outcome of constitutional causes. He thought it was criminal to persevere for years with the washing out of a stomach which had baffled careful treatment; operation was clearly demanded, and it was unfair to the patient, to the surgeon, and to humanity to wait until a condition of hopelessness had been reached.

EDINBURGH MEDICO-CHIRURGICAL SOCIETY.

MEETING HELD FEBRUARY 6TH, 1907.

DR. J. O. AFFLECK, President, in the Chair.

DR. CHALMERS WATSON read a paper on the

TREATMENT OF SOME DISEASES COMMONLY REGARDED AS OF GOUTY ORIGIN.

The conditions dealt with included migraine, "rheumatic" pains, recurrent nasal catarrh, and some vague and ill-defined symptoms often encountered after middle life. Dr. Watson cited in some detail a few illustrative cases out of several hundred such, which had come under his notice during the past five or six years; they were of the class commonly termed "gouty," and had proved obstinate to ordinary treatment. The line of treatment he had adopted consisted in restricting the allowance of proteid food, in using hydrotherapeutic measures, such as Turkish baths, freely, and in administering small doses of thyroid gland preparations. In his opinion the excessive ingestion of animal food threw an undue strain on the thyroid gland, tended to exhaust it, and thus indirectly affected the metabolism. The use of baths and measures directed towards increasing the functional activity of the skin, liver, and kidney promoted elimination, while the administration of thyroid stimulated metabolism. All clinicians, from Laycock onwards, agreed that there was a certain antagonism between gout and tuberculosis. Dr. Watson quoted descriptions of the typical "gouty diathesis," and the "strumous diathesis" in illustration of the different aspects of the subjects. Gout was a disease of well-grown vigorous subjects, and in its treatment the restriction of animal food was of special value. Tuberculosis, on the other hand, was a disease of less developed and less robust subjects, and in its treatment special value attaches to the use of a great excess of animal proteid food, as in zomotherapy. In the speaker's opinion, the subjects of inherited or acquired gout had acquired from their environment, which included diet, an abnormally active thyroid gland, working at high pressure, and liable to become exhausted. Subjects predisposed to tuberculosis had an inactive thyroid glandular system. The views formulated by the author on the basis of clinical observation had received confirmation from his experiments on animals. By feeding animals on a diet containing an excess of proteid food he had been able to modify the structure and function of the thyroid gland and other organs, and to produce in the offspring of meat-fed animals clear evidence of an altered functional activity of the same glands. The animals used for the experiments were rats, which were omnivorous, and, under certain natural conditions, as, for instance, near slaughterhouses, lived almost exclusively on meat, so that it could not be supposed that the changes he was about to describe were merely due to an inadequate or unsuitable diet. Sections were then shown on the screen illustrating the changes produced by a meat diet—the thyroid was over-active, and gave evidence of having an undue strain thrown upon it; the kidneys were larger than normal, while the bone marrow showed islets of cartilage amidst the blood-forming tissue. The mucous membrane of the frontal sinuses was in some, but not all, cases, thickened and catarrhal. Appearances which were very similar were also found in the offspring of meat-fed animals. The next demonstrated the organs of an infant which showed very much the same appearances. The child was the offspring of a tuberculous mother, who for a considerable time before and during the pregnancy had been fed on large quantities of raw meat. The child died in its second year from anæmia, and the changes in the marrow and thyroid gland very closely resembled those formed in the young of meat-fed rats. During life the clinical picture indicated to Dr. Watson that the symptoms, which were otherwise obscure, were the result of exhausted functional activity of certain glands, notably the thyroid and bone marrow. Dr. Watson next referred to clinical facts, showing that the diathesis of a tuberculous child could be favourably influenced by a prolonged course of dietary with excess of animal food. He instanced such a case, when the child was at first typically of the tuberculous constitution, and later became robust and suffered from irregular gouty symptoms. He concluded by pointing out that convergent lines of experimental and clinical evidence showed that the offspring of gouty subjects ought to receive little meat, no red meat under the age of six, while the children of tuberculous parents ought from their earliest years to receive a liberal quantity of red meat in their dietary.

Drs. JAMES and WILLIAM RUSSELL discussed the paper. The latter said that all were agreed as to the advisability of restricting the amount of meat in these irregular gouty manifestations. He doubted, however, whether the administration of thyroid had much to do with it. As to the experimental work, he thought the observations made, whatever their interpretation might be, were of great interest.

Drs. **John Thomson** and **Stuart McDonald** read a paper entitled

NOTE ON TWO FATAL CASES OF ACUTE MENINGOCOCCAL CEREBROSPINAL MENINGITIS IN YOUNG CHILDREN WITH PATHOLOGICAL REPORT ON ONE OF THEM.

Dr. **William Elder** read notes on five cases of

ACUTE CEREBROSPINAL MENINGITIS

recently under his care in Leith Hospital. Both these communications were accompanied by microscopic demonstration of specimens, cultures, and an exhibition of the organs. Full abstracts will be found on pages 172 and 173.

Dr. **J. C. Dunlop** gave the stitistics of fatal cases of cerebro-spinal meningitis in Scotland as shown by the Pegister nouse returns. The disease had appeared in Glasgow in May, 1906, and about a dozen cases had been certified every month since; in December and January the numbers had gone up considerably. Lately, too, a few cases had cropped up in other towns. Moreover, the Airdrie district, Edinburgh, and elsewhere.

Dr. **Cullen** said that in New York during 1905 and 1906 there had been 4,000 cases, and over 3,000 deaths from cerebrospinal meningitis.

Dr. **James Carmichael** said that while he had acted as physician to the Sick Children's Hospital he had on more than one occasion observed a somewhat unusual incidence of cerebrospinal meningitis, never, however, amounting to an epidemic.

Dr. **Edwin Bramwell** said he had seen the Leith cases, and also those in the fever hospital in Glasgow. The general impression derived was that it might often be impossible to distinguish these from posterior basic meningitis, which should be looked upon as a sporadic form of the disease. While some of the cases in the Glasgow epidemic were acute, like those described, the majority ran a more protracted course, and a fair number were recovered from.

Dr. **Fowler** had had five cases under his care in the Children's Hospital during the past month, only one being acute. He drew attention to the fact that the diagnosis was not always apparent in the less acute cases, for, although stiffness of the back was always present sooner or later, it might be very slight during the first few days. As an example, he quoted the case of a child in whom no sign of meningitis was present until about the fourth day, and yet on lumbar puncture pus was present. He had tried intraspinous injections without benefit. Lysol seemed to do no harm, but he had seen unpleasant symptoms follow the use of collargol. In one fatal case there was evidence that the injection had reached the base of the brain, so that it was reasonable to suppose that intraspinous injection with some suitable antiseptic might be useful.

Dr. **Painy** confirmed the observation that spinal rigidity might be absent for a time even in fairly acute cases.

Dr. **Ritchie** discussed the bacteriological aspects of the question. He said that, for exactitude, something more than staining films was required. He did not think one could rely on the differentiate of the pneumococcus from the meningococcus by this means alone. In all probability many of the cases attributed to the pneumococcus were due to the meningococcus. Referring to the reaction of the organism to Gram's stain, he pointed out that a great deal depended on the exact way in which the staining was done. Unless the classical method of Gram-staining was adhered to, confusion would result, and no comparison was possible. He inclined to the view that the change from Gram-negative to Gram-positive as described by Dr. McDonald was due to an impure culture.

Drs. **Thomson**, **McDonald**, and **Elder** replied.

The ninth case of small-pox in Cardiff within the past few weeks was notified yesterday. A case discovered on Thursday may regarded as the most serious, as the patient is the wife of a tramway conductor—a man constantly in touch with the public. Dr. Walford, the medical officer, states that so far the primary and direct source of the infection is not known.

LIVERPOOL MEDICAL INSTITUTION.

Meeting held Thursday, January 31st, 1907.

The Vice-President, G. G. **Stopford Taylor**, M.D., in the Chair.

A NEW REFRACTOMETER.

Dr. **K. Grossman** exhibited a new refractometer similar in principle to Marple's sciascope, but comprising all the spherical lenses likely to be required in retinoscopy, without combination, arranged in double rows in four hand instruments. The instrument could also be used for ordinary estimation by means of test-types.

SYPHILIS OF THE LUNG.

Dr. **R. J. M. Buchanan**, in describing the various forms of congenital and acquired syphilis of the lungs, paid special attention to the so-called "phthisis syphilitica," and contrasted the morbid anatomy and clinical symptoms of that disease with those of pulmonary tuberculosis. He urged the necessity of more careful clinical examination in cases of lung disease in order that syphilitic affections might not be overlooked. An illustrative case under his care was related, in which the symptoms resembled those of pulmonary phthisis for a year; no tubercle was found in the sputum after repeated examination; discrete areas of infiltration were present in both bases, one in the left lung circular in shape and about the size of a small orange, the one in the right lung oval, and the size of a hen's egg. These masses resembled hydatids, but a diagnosis of gummata of the lungs was made, and subsequently a history of syphilis was obtained. On examination with the X-rays the masses were clearly defined. The expectoration was stained with Giemsa's stain for 18 hours, and spirochætes were found. Anti-syphilitic treatment resulted in amelioration of all symptoms and disappearance of physical signs; a gain of 16 lbs. in weight in three months was recorded, and the patient has been able to resume his work, and expresses himself as perfectly well.

Radiographs taken by Mr. Thurstan Holland before treatment were exhibited, showing the original gummata and diffuse mottling of the lungs, and others showing the gradual absorption of the gummata and disappearance of mottling after treatment with mercury and potassium iodide.

Mr. **A. Nimmo Walker**, referring to Dr. Buchanan's observation of bodies resembling the spirochæta pallida in the sputum of his case, in contradiction of the usual statement that they were absent in tertiary lesions, said that he had had the privilege of being shown, by Staff-Surgeon Bankart, R.N., a section of syphilitic liver stained with silver nitrate, in which the spirochæta pallida was clearly demonstrated. He also alluded to the difficulty of finding the spirochætæ in patients under the influence of mercury, and considered that recent observations pointed to the contagiousness of tertiary lesions and to the value of mercury in their treatment.

Dr. **A. G. Gullan** referred to a case of syphilis (lip chancre) of ten years' standing in a woman 35 years of age. For two years she had suffered from cough, hæmoptysis and loss of flesh. Dr. McDougal had found a gumma of the left sterno-mastoid, and infiltration of the left vocal cord. Under anti-syphilitic treatment the laryngeal symptoms cleared up, but some lung symptoms remaining, the patient was transferred to Dr. Gullan's care, who found impaired movement, dulness, diminished breath sounds, and a few moist râles over the first, second, and third left intercostal spaces in front. Repeated examination of the sputum for tubercle bacilli gave negative results. Syphilitic treatment alone was continued, and the patient, in the course of a few months, made an excellent recovery.

Dr. **Crace-Calvert** also spoke.

THE SURGICAL TREATMENT OF FOCAL EPILEPSY.

Mr. **Damer Harrisson** restricted himself, in dealing with this subject, to cases of true focal or Jacksonian epilepsy calling for direct attack upon the brain or its membranes, including craniectomy, and deeper work upon the parts thus exposed. He attributed the fact that the results of operations in the past had not been more successful to two causes, viz. (1) The relatively late period at which operations had been performed, years having elapsed while the family physician had been experimenting with drugs until the patient was one in whom the epileptic habit had been thoroughly established. (2) The adhesions resulting from operations upon the skull, membranes, and brain. In his own experience, the use of fresh egg membrane, as recommended by Leonard Freeman in 1898, had largely met the adhesion difficulty. In speaking of the technique of the operation, he said that he reflected a large osteoplastic flap in almost all cases, using the chisel in preference to other instruments for work upon the bone.

His paper was illustrated by 24 cases (with 31 operations) of whom six had died. Of the six deaths not one was attributable to the operation, but to the extremly bad condition of the patient at the time of the operation. Of the 18 recoveries, 12 were successful and six were relieved.

Dr. W. **Carter** thought Mr. Harrisson's paper was most valuable. He mentioned the case of a woman, æt. 30 years, who had been epileptic twelve years. The intervals between the attacks became shorter and shorter, till at length she passed into the status epilepticus. After consultation it was decided to operate. On the day preceding the consultation there had been 80 seizures—all medicines having been omitted for a day in order that everyone might see her as she was when uninfluenced by drugs. The only localising indications were slight drooping of the right eyelid, and a reported commencement of the attacks in the left foot. Dr. William Alexander removed a piece of the calvarium four and a half inches long by two and a half inches broad from over the right Rolandic area, and as the dura mater looked healthy, though it bulged to the level of the scalp, it was agreed not to incise the membrane. The result was most satisfactory. The patient became conscious, intelligent, and bright. Some time later she was married, and remained free from attacks for twelve years. The next, and so far as was known, the only attack occurred at her husband's deathbed. Dr. Carter was present, and had her removed to a small ward, where she soon recovered consciousness and returned to her home. Nothing had been heard of her for three years. It was the belief of the entire hospital staff that she could not live many days, and that it was due to the operation that she was able to live an active and useful life for many years.

Dr. Stansfield and Dr. J. H. Abram also spoke.

CORRESPONDENCE

FROM OUR SPECIAL CORRESPONDENTS ABROAD.

GERMANY.

Berlin, Feb. 10th, 1907.

At the Verein für Innere Medizin, Hr. Leo Hirschlaff showed a case of

Influenza Encephalitis.

The patient was a woman, æt. 28, the daughter of a drinker. She was very delicate after the usual infantile diseases, and was unable to run about until her fifth year. Menstruation first appeared at eighteen, and since then her health has been good. Three weeks before the commencement of the present illness she had a slight attack of influenza, but she was not obliged to give up work. On December 1st she suddenly felt sick, with heaviness of the right arm and leg; she also noticed a peculiar failure of sight—she could only see the half of people. She had no headache, but her mental faculties were somewhat astray; she was confused, and her speech was thick. The patient was admitted into hospital, when it was ascertained that her temperature was normal. A diagnosis of hysteria was made. First of all rest in bed was ordered, and then electricity. Improvement gradually set in, and the patient was discharged in about six weeks. Six days afterwards the patient came under the speaker's care. An examination showed that the right pupil was slightly wider than the left; it reacted to light and accommodation; there was hemianopsia, the ophthalmoscope showed slight shading of the papillæ of the right eye, with paleness of the right half, perhaps indicating a neuritis. There was no limitation of the field of vision. The hearing power was slightly diminished on the right side, and there were the remains of an otitis. There was also paresis of the lower facial, pharyngitis, palatal movements good. The sensibility in both arm and leg slightly diminished, but not in the face and trunk. The right arm was slightly thinner than its fellow, and the power diminished; the skin and tendon reflexes on that side were also lowered. The power of the right leg was also diminished. Articulation was imperfect. Primary memory was intact, secondary not so good. General intelligence was good, but reckoning even in its simplest form was impaired. The diagnosis he had formed from the condition present was influenza-encephalitis. In general the prognosis in this form of disease was good.

The Opium-Bromine Treatment of Epilepsy.

Dr. Kellner, the Director of the Hamburg Institute for Idiots and Epileptics, has published his observations on this method of treatment in the *Munch. Med. Wochensch*, 48, 1906. Amongst all the drugs made use of, bromine plays the leading part, he says. In almost every case the frequency and violence of the symptoms can be diminished by the systematic use of the medicine in doses not too small. But the hope of bringing about complete cessation is not fulfilled, and he has never seen an interval of more than a year between attacks in a single case. He then made a trial of the combined opium and bromine treatment, and he has become convinced that in this we possess the most reliable means of treating this illness.

He has employed this form of treatment for the last ten years, and in the following manner. The patient for fifty days gets a dose of ext. opii three times a day beginning with 0.05 grm. Every second day the dose is increased by 0.01 grm., so that at the end of the fifty days the largest dose has reached 0.29 grm. three times a day. The dose given on the fifty-first day is 0.3 grm.; it is given once, and with that the opium treatment ends, and immediately on this the bromide treatment begins. At midday and evening of the same day a dose of 2 grm. of mixed bromides is given, the mixture consisting of pot. brom. 1 part., sod. brom. 1 part, and ammon. brom. ½ part. On the fifty-second and fifty-third days 6 grm. of the mixture are given; on the fifty-fourth and fifty-fifth, 7; on the fifty-sixth and fifty-seventh, 8. From the fifty-eighth day 9 grm. are given, and continued a long time. The medicine is always given in a glass of fresh Seltzer water.

During the opium treatment the patient gets a tablespoonful of a 1 per cent. hydrochloric acid solution three times a day, but it is observable that this is not necessary, as constipation never follows the use of large doses of opium. Bismuth takes the place of the hydrochloric acid if desirable. Naturally the diet must be light and free from spices, with a preponderance of vegetables. The patient must move about a good deal in the open air, and the writer has always insisted that during the period of opium treatment the patient shall be free of all work—school work or any other. A third factor in the treatment is the baths, which are given as follows:—On the first day a bath at 24° C. of ten minutes, on the second day one at 23° C. of nine minutes, on the third day one at 22° of eight minutes, and so at the eighth day a bath at 17C. and of three minutes is reached. It remains at this up to the fifteenth day, then from the sixteenth to the twenty-third a bath at 17° C. is given for four minutes, from the twenty-fourth to the thirty-first one of 17° C. and five minutes, from the thirty-second to the fiftieth a bath at 17° C. for six minutes.

This treatment is not followed out in weak patients or those whose minds have already given way. It has been limited, therefore, to those who have retained some mental power or to epileptics who were otherwise in fair health, and the dose stated is reckoned for a full-grown healthy man and not for a child.

The results are as follows: Excluding five still under treatment, eighty have undergone the course. In sixteen (20 per cent.) of these the treatment had to be interrupted, as the opium could not be borne. In 6 (7.5 per cent.) the treatment failed; a diminution in frequency and severity of attacks was noted in 23 (29 per cent.) A considerable improvement in that the attacks return only at intervals of several months or their place was taken by attacks of giddiness, thirteen cases (10 per cent.). In twenty-two cases (27.5 per cent.) the patients have remained completely free since the treatment, in one case eight months after completion of the course; the others have been free for from two to six years. For success in this treatment it is very important that the patient should lead a very quiet life, free from all excesses both during and after treatment. When epilepsy comes on first later in life the prognosis is bad. Those cases that have remained free from the disease have all been between 15 and 30 years of age.

AUSTRIA.

Vienna, Feb. 10th, 1907.

BODY TEMPERATURE AND URINE.

ENGLANDER gave the members of the Gesellschaft a long paper on the value of taking the temperature of the body from the urine. This idea is rarely expressed in medical literature, although many authors refer to it as a possible means of measuring the temperature. The greatest objection to its utility is the rapid cooling of the secretion after emission, as the temperature of the air and the receptacle quickly alter the temperature. To obviate these difficulties he arranged his method into:—(1) Passing the urine directly into a receptacle without coming into contact with the air; (2) Selecting a suitable material for the receptacle which would not require the warming of the receiver; (3) Measuring the temperature in a current of urine, and not standing. The material Engländer used for a receptacle was strong filter paper. This form of vessel absorbs the urine and soon passes it through the wall of the receptacle, and thus prevents the cooling of the inflowing urine. With a funnel-shaped vessel of filter paper and a maximum thermometer, after 10 to 12 seconds, in which time 100 to 150 cubic centimetres will have passed through, the exact temperature of the body will have been registered. Engländer has now made use of this method of taking the temperature during the last two years, which comprises 250 patients, with the happiest results. He has tabulated the different temperatures for the two years, and finds that the next reliable guide for the temperature is the anus. The widest differences are observed during the summer months. He finds the axillary temperature very fallacious. He has long suspected this deviation, and determined to prove it by other collateral evidence. This method of urine testing was of great service in the outdoor department, where the patient could not be kept in bed sufficiently long to obtain anything like a reliable temperature.

Winternitz considered this method of taking the body temperature was a great advance on our antiquated and very incorrect manner of taking temperature, which was often an important factor in the correct diagnosis of a case; besides, the rapidity by which it can be obtained adds immensely to its value. All accurate observers acknowledge the axilla temperature to be very faulty, but tolerate it on the grounds of custom. He saw one objection to Engländer's method in females, and thought the vagina or rectum would be more practical.

Teleky thought the rectal temperature was sufficiently reliable, and could be taken in a few minutes. To this Engländer asked how he could rely on a temperature in the anus blocked with a large fæcal mass, which was often the case in outdoor patients.

MAZONUS' THEORY OF PERCUSSION.

Hamburger contributed a paper on the different theories of percussing the chest. He concluded in favour of Mazonus', which is a combination of Williams' and Skoda's. The percussion sound was due to the vibration of the costal walls and the air contents of the lung. Weil further contends that the intensity of the percussion sound is not only due to the amplitude of the vibrations, but depends largely on the mass—that is, the lung tissue and the contained air. He values the deeper sounds and not the superficial. The relative dulness of the liver is not entirely due to its peculiar vibration as to its proximity to the costal wall. The consideration of this superficial concussion has not only a theoretical and scientific interest, but a practical side also, such as in children where the costal walls are more yielding and elastic, and thus give a higher vibratory sound in the thorax wall of the child. This result makes it more difficult for the delimitation of the organs in a child than in an adult.

ISOLATED ASTHMA.

Riehl gave the history of four cases of ill-defined asthma which he described as "Macroscopic Asthma Spiralen." The disease commences with unpleasant forebodings, loss of appetite, heaviness, general malaise, and slight fever, followed by cough, spitting, and pain in the chest, with difficulty in breathing. Objective symptoms are disturbances of the nervous system, harsh breathing in the lung, looseness of the mucus in the region of the large bronchi, moist râles with difficulty of expectoration and no rhonchi. A large number of eosinophile cells were present in the sputum, but no Charcot Leyden's crystals. The most effectual treatment was morphia injection and iodide. He considered these variant bronchial asthma cases to depend on some changes in the bronchial ramifications not yet clearly understood.

FROM OUR SPECIAL CORRESPONDENTS AT HOME.

SCOTLAND.

NEW PRINCIPAL OF GLASGOW UNIVERSITY.—It has been officially announced that the King has been pleased to appoint Dr. Donald MacAlister, Fellow of St. John's College, Cambridge, to this office. The new Principal is about 53 years of age; he is a native of Perth, and was educated at Aberdeen, Liverpool, Cambridge and Leipsig. In his university career he was especially distinguished in mathematics, having been both Senior Wrangler and Smith's Prizeman. He was for a time mathematical master at Harrow, and in 1879 became lecturer on Natural Philosophy at St. Bartholomew's Hospital. In 1887 he was selected to give the Goulstonian Lectures at the Royal College of Physicians, and is at present Linacre Lecturer of Physic, and Director of Medical Studies at St. John's College, Cambridge. He succeeded Sir William Turner as President of the General Medical Council, and in that capacity has shown great administrative and business ability. It is somewhat remarkable that two successive presidents of the General Medical Council should within so short a period have been appointed to the Principalship of Edinburgh and Glasgow Univeristies.

CEREBROSPINAL FEVER.—Cases of cerebrospinal meningitis continue to crop up throughout Scotland, but, except in Glasgow, there cannot be said to be an epidemic of the disease. Two cases have been reported this week from Haddington, five from Falkirk, three from Kirkcaldy, two from Greenock, five from Paisley, two from Aberdeen, while there have been several fresh cases both in Leith and Edinburgh. In a memorandum on the subject, Dr. A. K. Chalmers, the medical officer of health for Glasgow, suggests that the increased prevalence of the disease may have some relation to the exceptionally low temperatures registered during the week ending December 29th and January 26th.

ROYAL MEDICAL SOCIETY'S ANNUAL DINNER.—Prof. Osler, Oxford, was the guest at this year's annual dinner, which was held in the Society's Hall, on

February 7th. Dr. Drennan presided, and the company included the Lord Advocate, the Solicitor-General, Dr. Cameron Lees, Professors, Schäfer, Croom, Annandale, Chiene, Cuningham, the Presidents of the Royal Colleges of Physicians and Surgeons, and a number of other well-known Edinburgh medical men. In reply to the toast of his health, Professor Osler said he was a pure Celt. There were two types of Celts—one born under Saturn, a most unhappy person; he knew no more unfortunate mortal than the Saturnine Celt—he had no option in this world between Scots whisky and some form of Presbyterianism. That was not the Celt he was. He lifted up his hands occasionally and thanked heaven the Celts who were his forbears were born, not under Saturn, but under Mercury. For that gave a man the most fortunate thing in life—an optimistic temperament. To that he attributed a great part of whatever success he might have had; another element was a love of work. No one naturally liked work, man was born idle; but there was something in the profession of medicine through which, if you once got inoculated with it, you got a love of work, and with that, a love of your fellow-creatures. Prof. Osler next proposed the toast of the Royal Medical Society. In the course of his speech he said that perhaps with the single exception of the Royal Society of England there was no society in the world to-day which had so distinguished a list on its roll. Amongst the names of the eighteenth century he saw William Cullen, William Saunders, a professional son of Cullen, who taught the Londoners how to teach clinical medicine, Whytt, and Currie. It was not the names of these men that touched him closely, for to his astonishment he found that the men he had learnt to reverence in the United States and Canada were members of the Society. Benjamin Franklin was a member of the Society, and took back to Philadelphia the traditions and associations, mental and moral, received in that Society. On the following day Professor Osler addressed the students in the Macewan Hall on cerebrospinal meningitis. After a short lecture on the topic, he spent the remaining ten minutes of the hour in inculcating two maxims which should lead to honour and happiness. The one was the value of steady, not desultory work; the other the absolute necessity for living on good terms with one's professional brethren, and never quarrelling with them on any provocation whatever.

Scotch Poor Law Nurses.—In future the Local Government Board proposes to hold periodical examinations for poor law nurses, and to grant diplomas to those who qualify. According to a memorandum just issued, probationers must have been of good character, and have received a fair general education; the latter will be tested by the Board. The training will extend over three years, during which time the nurses will have to attend lectures by the medical staff. The examination subjects will include anatomy and physiology, hygiene and dietetics, nursing of medical and surgical cases, midwifery, and will be both written, oral and practical. The scheme will ensure that the Poor Law nurses receive as good a course of training, and will be as fully qualified, as those educated at any other institution.

LETTERS TO THE EDITOR.

"PROFESSIONAL MISCONDUCT" IN THE LAW COURTS.

To the Editor of the Medical Press and Circular.

Sir,—A year or so ago a distinguished Judge of the High Court declared that "medical law was in a state of fog." Everybody who knows enough about the matter has been aware of this for a long time, and to such persons the judgment of Mr. Justice Warrington in the case of Clifford *v.* Timms, commented upon in your leader of February 6th, can have caused no surprise. It is useless to find fault with a judge who has brought to bear an acute and practised intellect in interpreting laws with the imperfections of which he has nothing to do; and it is useless to rail at the Medical Council, which cannot go beyond the narrow statutory limitations imposed upon it. If there is to be blame for the present situation, the blame must fall upon the profession itself. Here are some 30,000 men upon whom the State lays onerous obligations before its accords them legal status. The legal status is virtually nominal. Appointments in the services of the State are restricted to legally qualified men; but this restriction is for the protection of the public. Beyond this the profession possesses neither privilege, power, nor protection. It can be conclusively demonstrated that regulation of the profession under laws similar to those provided for other professions such as solicitors—laws which work perfectly smoothly and effectually—would confer vastly greater advantages upon the public than upon the profession. The case for medical law reform is overwhelming; it needs only to be fully and clearly stated in order to be accepted by responsible politicians and statesmen. As I have over and over again urged in your columns, and in those of your medical contemporaries, the only available method of establishing the claims of the profession lies through the medium of a Royal Commission. This would be necessary even if the profession had on its side the newspaper press or a minority of leading papers; it is more than ever necessary now that the whole press, with extremely rare exceptions, is deriving one of the main items of its income from publication of quack advertisements. These papers prefer for gain to abet a nefarious traffic rather than to perform their ostensible duty in safeguarding the interests of the public. The evidence produced by a Royal Commission would, among other things, put an end to the present unholy alliance between the newspaper proprietor and the fraudulent quack. That it would in due course lead to a satisfying reform of medical law, I for one do not doubt. If this desirable consummation is to be achieved, the profession must concentrate its energies, and prepare for the needful sacrifices. Money will be wanted. A considerable expenditure would be needed in establishing the preliminary demand for a Commission, and, the demand acceded to, a much greater sum would be called for in preparing and presenting the case. Altogether a good many thousands of pounds would be necessary—perhaps a sum representing an average contribution of between 10s. and £1 from every active member of the profession. If the profession cannot be roused to help itself in the way I suggest, its case must remain hopeless, and the situation had then better be tolerated in dignified silence without futile discussion and expression of discontent, which cannot be satisfied by any available method save the one which the profession itself declines to adopt.

I am, Sir, yours truly,

Henry Sewill.

February 7th, 1907.

"THE SURVIVAL OF THE UNFIT."

To the Editor of the Medical Press and Circular.

Sir,—Assuming the correctness of the report to the Bedlington Council in a recent issue of your journal, one would like to ask Dr. Trotter more fully to justify and explain the statement you quote:—"When one finds the Legislature passing laws for the benefit and education of feeble-minded, defective children, one is inclined to wonder whether we are not a nation of fools, whether we should not benefit the nation more if we followed the custom of the ancient Spartans, and stamped such types out altogether." Surely, Sir, the proper counsel to be offered by the scientific physician is that the manufacture of the unfit should be put a stop to, not that the wretched products of bad breeding for which the State—the whole nation—is to blame, should be destroyed. Syphilis, tuberculosis, rickets, typhoid fever, alcoholism, ignorance of mothers, criminal cruelty by parents, wholesale neglect of sanitary laws by authorities charged with their administration—all these things and a score more of the same sort rush to one's mind when one considers the question of degeneration. Nearly all the causes of physical and mental unfitness are known; when these are removed the methods of Sparta will no longer need consideration. I am, Sir, yours truly,

Evolutionist.

February 2nd, 1907.

ASSOCIATION OF MEDICAL MEN RECEIVING RESIDENT PATIENTS.

To the Editor of The Medical Press and Circular.

Sir,—May I call your attention to a recent remarkable utterance of Judge Philbrick in the course of a County Court claim brought by the above Association against one of its members. The Judge went out of his way to cast absolutely unfounded and gratuitous aspersions upon a society of medical gentlemen formed for a perfectly legitimate purpose. Each member who obtains a resident patient through the society agrees to pay so much commission, which goes into a common fund. Not a single penny is paid to any officer, and members make no profit out of the transaction. Why, then, should a judge speak thus slightingly of a body of gentlemen of whose aims and organisation he must be profoundly ignorant? I trust a question will be asked upon the matter in Parliament.

I am, Sir, yours truly,

An Old Member of the Association.

[This matter is commented upon in our opening columns.—Ed. "M. P. and C."]

OBITUARY.

EDMUND COCKEY, M.R.C.S., L.S.A.

Mr. Edmund Cockey, the doyen of Frome medical practitioners, died on February 3rd, in the 90th year of his age. The deceased gentleman was in practice in that town for nearly 60 years, and for 55 years and 7 months held the post of medical officer at the workhouse, being appointed in October, 1843, and resigning in May, 1899. He was a member of one of the oldest and most highly respected of Frome families. The bells in many of the churches in Somerset testify to the skill of former generations of Cockeys. Mr. Edmund Cockey was medically educated at St. Bartholomew's, and took the qualification of M.R.C.S and L.S.A. as long ago as 1842.

JOHN GUEST GORNALL, M.A., M.B., B.C.Cantab., D.P.H.

We regret to announce that Dr. J. Guest Gornall, medical officer of health for Warrington, died at Grappenhall on February 4th. Dr. Gornall had been in failing health for a considerable time, and two months ago the Town Council granted him a long leave of absence in order that he might recuperate. Dr. Gornall only returned from Llandudno last week, and for the past few days had suffered from asthma. He was appointed medical officer, to succeed his father, in 1901. As medical superintendent of the smallpox hospital, he successfully coped with an epidemic which occurred in the town between 1892-4. Dr. Gornall was educated at Cambridge and St. Thomas's Hospital, and graduated M.A., M.B., and B.C. at the former University in 1892. He took the D.P.H. in 1896.

SPECIAL ARTICLE

UNIVERSITY EDUCATION IN IRELAND.

During the past week several important meetings have been held in connection with Mr. Bryce's scheme for the revolution of University education in Ireland. On Monday, January 31st, a largely attended meeting of the Senate of Dublin University was held, the Vice-Chancellor in the Chair, the following resolutions were unanimously adopted:—

"That we are of opinion that the scheme which Mr. Bryce outlined in his speech of January 25th, 1907, would be fatal to the best interests of liberal university education in Ireland, as well as unjust to Trinity College, and we are determined to oppose it by every means in our power."

"That the Senate appeals to all graduates of Dublin and other universities, and to all those, without distinction of party, who value freedom in research, teaching, and publication, to assist in maintaining unimpaired the constitution and position of Trinity College, Dublin, which, in the unanimous opinion of the Commissioners, 'as it stands to-day is a noble institution for the maintenance of sound learning, not unworthy of its great traditions and of the affection and veneration with which it is regarded by its children.'"

"That we protest against Mr. Bryce's scheme, because it provides, and can provide, no adequate safeguards against the introduction of sectarian divisions into the administration of the university."

On Wednesday the Council of the University met, and it was unanimously resolved—"That we are of opinion that the scheme which Mr. Bryce outlined in his speech of January 25th, 1907, would be fatal to the best interests of liberal University education in Ireland, as well as unjust to Trinity College, and we are determined to oppose it by every means in our power."

A public meeting convened by the Galway County Council was held on Friday in Galway, the Archbishop of Tuam in the chair, to consider the position of the Queen's College, Galway, as outlined in Mr. Bryce's speech. The following resolutions were passed:—

"That this public meeting, representing all sections and varied interests in the town and County of Galway, and the Province of Connaught, unites in a protest against the proposed exclusion of Galway as a Constituent College in the New University scheme outlined by Mr. Bryce."

"That it is the opinion of this meeting that if Queen's College, Galway, were given an equal position with the other Queen's Colleges, and were to have its constitution so modified as to bring it into greater harmony with its surroundings, and to make it acceptable to all the people of Connaught, there can be no question that it would quickly become an efficient University College, and would prove the prosperous centre of intellectual life and educational activity for the Province of Connaught."

At a meeting of the Governing Body of the Catholic University School of Medicine held on Friday, the Governors had before them the following resolution, unanimously adopted by the Medical Faculty at their meeting on the 2nd inst.:—"That a settlement of the University question on the lines laid down by Mr. Bryce would be acceptable to this Faculty provided that the details of the Bill are satisfactory to the Catholic hierarchy and laity, and that a real equality as to equipment and autonomy, as compared with Trinity College, Dublin, is given to the new college." The Governing Body unanimously approved of the resolution and directed that it should be published.

The Committee of Irish Catholic Laymen have adopted the following resolution:—"That, while desirous of expressing our gratification at the intention of the Government, as announced by Mr. Bryce, to provide for Irish Catholics collegiate education within the University of Dublin, we consider it premature, without fuller details, to put forward any opinions as to other parts of the scheme."

Lastly, the Corporation of Dublin has passed the following resolution, on the motion of Dr. McWalter:—"That as the Town Council of Edinburgh has been for centuries represented on the University of Edinburgh and with great advantage to that institution, the Corporation of Dublin requests that it shall have adequate representation on the governing body of any reconstituted university in Dublin. And, furthermore, this Council cannot accept as final any settlement of the university question that does not provide higher education for the sons of the workers of the country."

Weekly Summary of Medical Literature, English and Foreign.

Specially compiled for The Medical Press and Circular.

RECENT GYNÆCOLOGICAL LITERATURE.

Pathology of Chronic Metritis.—Fletcher Shaw (*Journ. Obst. and Gyn.*, Feb., 1907). In this paper the author gives the results of the microscopical examination of 38 uteri extirpated for chronic metritis alone, 7 extirpated for chronic metritis with some concurrent disease, and for comparison 23 normal uteri and 50 curettings. The conclusions arrived at are as follows:—Chronic metritis is a simple hypertrophy of the mesometrium, and is not a connective tissue hyperplasia. The percentage of connective tissue varies considerably in the different specimens of chronic metritis, but many normal multiparous uteri possess an equal or even greater proportion of connective tissue. The vessel changes are variable, similar affections being found in normal uteri. There is no evidence of active inflammation as shown by small-celled infiltration or cicatricial tissue. Chronic metritis is a slowly progressing affection of the uterus, first causing enlargement, and later hardness of the organ. It is never a primary affection, being usually secondary to chronic endometritis, but may be associated with any pelvic or uterine disease which leads to increased uterine contraction or vascularity—*i.e.*, fibroids, tubo-ovarium inflammation, carcinoma, prolapsus. The age of the patients is on the average about 38, well below the average age at which the menopause occurs, thus proving that the climacterium is not the usual factor in the complaint. The symptoms are mainly those of the primary disease, and in the early stage chronic metritis is indistinguishable from chronic endometritis. At a later period the great increase in the size of the uterus may produce pain in the hypogastric and iliac regions, due to traction on the broad ligaments and sacralgia. The diagnosis depends largely on the results of treatment. In the early stage of the affection all the symptoms disappear after dilatation and curetting the uterus, thus demonstrating that the endometritis is the primary cause. In chronic metritis and endometritis, local treatment of the endometrium may fail to relieve the symptoms, this being probably due to re-inauguration of the endometritis. Treatment consists of living a simple hygienic life, regularity of bowels, douching and curetting. These methods fail in some cases, and then hysterectomy is called for.

F.

The Radical Abdominal Operation in Carcinoma of the Cervix Uteri.—Wertheim (*Surgery, Gyn., and Obst.*, January, 1907).—After describing in detail the technique of his operation for carcinoma of the cervix, the author gives his histological findings. In 28 per cent. of the cases operated on the regional lymphatic glands were affected with cancer. The cancerous glands were always enlarged, and generally very considerably so; only in a few cases was the enlargement inconsiderable. In the elongated spindle-like glands, which, so to speak, only represent a thickening of the lymphatic ducts, carcinoma was never found. In a further 30 per cent. of the cases the glands were more or less considerably enlarged, but no carcinoma was found in them—only hyperplasia and infiltration. Places of predilection for the appearance of cancerous glands were the regions between the external and internal iliac artery, and the obturator foramen. In the great majority of cases, where diseased glands are found, they are cases of advanced cancer; in only a few of the cases were they present in the early stage. The histological examination of the parametrium showed that in 22 per cent. of the cases this tissue, though when investigated it was found to be soft and distensible, proved to be cancerous. On the other hand, in about 14 per cent. of all cases, though there was considerable infiltration, no carcinoma could be found. In answer to the question: In what stage of the disease are the lymphatic glands affected by cancer? it appears from our investigation that in 10 per cent., notwithstanding the absence of cancer in the parametrium, the glands were cancerous; and, *vice versâ*, in 27.5 per cent., though cancer existed in the parametrium, the glands were free from it. In 40 per cent. the parametrium and lymphatic glands were free from cancer, and in 20 per cent. both were affected. The author finally states that, in spite of many opinions to the contrary, he persists in retaining his view that carcinoma is never contained in lymphatic glands unchanged in size, shape, or consistence.

F.

A Cæsarean Section for Prolapse of the Cord is recorded by Pekarskaja (*Zentralbl. für Gyn.*, 1907, Nr. 4). His patient, a primipara, æt. 24, told him when he first saw her that the membranes had ruptured four days previously, and that she had had pains for two days. The pelvis measured 28.5, 26.5, 25, 17; conj. diag., 9.2-9.5; conj. vera, 7.25-7.5 cm. A generally contracted rachitic pelvis. The presentation was first vertex, head movable above the brim, cervix admitted one finger, and the prolapsed pulsating cord was felt. The membranes were ruptured; the fœtal heart good. As the cord could not be replaced, and the parents were very anxious that the child should live, a Cæsarean section with Fritsch's transverse fundal incision was performed, and a living boy, 50 cm. long, and 2,920 g. in weight, was extracted. During the first nine days of the puerperium the patient's highest temperature was 38.3 deg.; pulse, 94. On the 25th day the woman left the hospital in excellent health, her child weighing 3,960 g. During her second pregnancy premature labour was induced in the 33rd week. The child, which was 1,900 g. in weight, and 44 cm. long, only lived 4½ hours.

G.

Episiotomy.—Prokofjewa (*Zentralbl. für Gyn.*, 1907, Nr. 4) incised the perineum in the raphe during delivery in 23 cases. One was a multipara, the others primiparæ varying in age from 20 to 40. The incision was made with an ordinary scalpel when the head was passing over the perineum. The length of the incision varied between 2 and 5 cm., according to the requirements of the cases. The author never found the incision extending into a tear. Immediately after the child was born the incision was united with silk sutures and healed in every case by first intention. The author concludes that when there is not sufficient elasticity of the perineum, and the size of the child's head is large, episiotomy performed at the right moment prevents extensive ruptures of the muscles of the pelvic floor.

G.

The Treatment of Uterine Myomata.—A. Martin (*Zentralbl. für Gyn.*, 1907, Nr. 4) records the operative treatment adopted by him during 6½ years. Among his hospital patients suffering from myomata, operation was performed in 84 per cent. of the cases, 69 undergoing the radical operation, 88 the conservative. Among his private patients 76 per cent. were operated on, 65 radically, 59 conservatively. There were therefore 134 women on whom the radical operation was performed. Of these ten died (7.4 per cent. mortality). Among the 147 on whom the operation was conservative, 8 died (5.4 per cent. mortality); of the 124 who survived the radical operation, 94 have been since under observation; 9 have reported on themselves by letter. Of the 139 who survived the conservative operation, 102 have since been under observation; 15 have reported themselves by letter. Those who had the conservative treatment feel better than those who had the radical. As regards recurrence, the author reports 12 cases from his Berlin material, but not a single case among his material in Greifswald. In Berlin the author performed 270 enucleations with 4.4 per cent. recurrence. As a result of his observations the author concludes that conservative myomectomy has justified itself. In cases of uncomplicated myomatous disease, he operates by the conservative method up to the climacteric, so long as enough uterine tissue capable of performing its functions can be preserved for the patient. He lays stress upon the necessity of careful examination of the endometrium at the same time. The vaginal route has given him by far the best results. G.

A Contribution to the Pathology of the Lutein Tissue is made by Ulesko-Stroganowa (*Zentralbl. für Gyn.*, 1907, Nr. 4). In a case of total extirpation of a fibroid uterus a cystic ovary was also removed. When this was opened teeth and hair were found in it, and in the ovary near the cyst a piece of tissue was discovered which, according to position, was like a corpus luteum, but from external appearances looked like fat tissue. In another case, in which the patient was four months pregnant, a dermoid was removed per vaginam, and here also a piece of tissue similar to that which has just been described was discovered. Both were examined microscopically by the author. A great increase in the lutein cells, together with fatty degeneration and infiltration of them, was discovered. Considering the histo-genesis and the peculiarities of lutein tissue, it must be regarded as a particular species of epithelial tissue. It develops itself in the ovary in association with the different changes in the sexual organs which are accompanied by long-continued hyperæmia, whether it be pregnancy, myomata or any other disease. These conditions were present in the cases described by the author. In addition to this, it is also the author's opinion that the characteristic fatty contents of a dermoid has much significance in the degeneration of lutein tissue. The accumulation of fat must be looked upon rather as a fat infiltration, and not as a degeneration. G.

Retention of the Membranes.—Rissmann (*Monatsch. für Geb. und Gyn.*, Bd. 24, Hft. 5) advises active treatment for this occurrence. The danger of sepsis alone should prevent one leaving the expulsion of the membranes to the natural forces, which may not work, or at any rate very often work too late. Besides this, owing to the retention, the involution of the uterus is slower and not so complete, and now and again considerable hæmorrhage may occur. As treatment the author advises that the uterus should be made to contract as much as possible, and that it should be then compressed by a heavy sandbag or an icebag laid on the abdomen. After six to twenty-four hours, an attempt should be made to express its contents. If, in spite of this, membranes are still retained, they must be removed instrumentally. Retention will the more seldom occur the more expectant the treatment of the placental stage is. G.

Forty Cases of Eclampsia are described by Pomy (*Zentralbl. für Gyn.*, 1907, Nr. 2). They occurred from January 1st, 1888, to December 31st, 1905, among 3,282 deliveries in the Göttinger Frauenklinik—*i.e.*, 1.2 per cent.; 32 of the mothers, or 80 per cent., were primiparæ; 8, or 20 per cent., multiparæ. Among the latter 3 were ii.-paræ, 3 iii.-paræ, 1 iv.-para, 1 xiii.-para. As regards age, from 15-20 years there were 13 i.-paræ; from 21-25 there were 10 i.-paræ; from 26-30, 1 multipara and 6 i.-paræ; from 30-35, 2 i.-paræ, 2 multiparæ; from 36-40, 2 multiparæ; from 41-45 1 i.-para, 2 multiparæ; from 46-50, 1 multipara. In the years 1890-1892, 1894, 1896, and 1899 no case of eclampsia was observed, while in 1901 nine cases; 1904, seven cases; 1905, seven cases occurred. During the months from October to February fewest cases occurred. The number of convulsions varied between 1 and 40. In the majority of cases not more than 5 convulsions were observed. The cases occurred as follows:—Inter-graviditatem, 10; inter-graviditatem et intra-partum, 3; inter-graviditatem et post-partum, 3; intra-partum, 12; intra et post-partum, 5; post-partum, 7. Premature labour occurred 10 times; 5 times there was general contraction of the pelvis. In one case albumen could not be discovered; otherwise it varied between ½ per cent. and 4 per cent. In one case the patient had already suffered from eclampsia 10 years previously. The maternal mortality was 20 per cent.; 7 primiparæ, 1 multipara. Death occurred ante-partum, 1; intra-partum, 1; post-partum, 6. The fœtal mortality was 50 per cent.; of those dead nearly half were premature; 6 died ante-partum, 11 intra-partum, 4 post-partum. As regards treatment, at the beginning chloroform and diaphoresis were most adopted, venesection seldomer. As time went on, operative treatment came gradually more and more into use, and the greatest stress was laid on the fact that the delivery should be completed as quickly as possible. Forceps or version and extraction were performed where they were possible. When the cervix admitted a finger, the rubber bag was used for dilatation. To dilate the cervix enough to admit the bag, iodoform gauze or Hegar's dilators were employed. In several cases in which the maternal soft parts were completely unaltered, the classical or the vaginal Cæsarean section was performed. Bossi's dilator was never employed. G.

Atresia Vaginæ in a Married Woman.—(Henderson, Aberdeen, *Brit. Med. Journ.*, Jan. 19th, 1907). Under this heading is recorded the history of a woman, æt. 30, a v.-para, whose last confinement took place on March 23rd, 1905. She stated that all the children had been born at full, and never had had instruments used, but that the last labour had differed from those preceding by being prolonged, the child being "big." She was out in a week's time, but was longer in picking up than usual. The infant was suckled for ten months, and was weaned in the beginning of February; but, contrary to the usual course of events, the patient noticed there was no return of the menstrual flow before weaning. When seen a month later, she complained of bearing-down pain accompanied by dyspareunia. On inspection of the abdomen, a pear-shaped tumour, with its long axis vertical, was noted in the middle line. It extended to 1 in. above the umbilicus. It did not move with respiration, and was tender on deep palpation, and the percussion note was dull. On vaginal examination it was found that the finger could not be inserted for more than 1 to 1½ in., but per rectum a large fluctuating tumour could be felt bulging through the anterior wall. On March 21st, 1906, she was sent in the Aberdeen Royal Infirmary, and, after examination under chloroform, which showed that the vagina was occluded by cicatricial tissue, it was concluded that the lower end of the tumour consisted of retained menses; the pear-shaped tumour the uterus, and that the atresia was due to lacerations produced during the last labour. The following day a large quantity of reddish-brown fluid escaped per vaginam, and the flow continued for several days, unaccompanied by a rise of temperature, the tumour growing gradually smaller. Three weeks later normal menstruation set in, the uterine tumour having disappeared. About seven weeks after admission, the operation was undertaken to restore the vagina. A pin-hole opening at the apex of the cicatrix was seen, and on free incision of the latter a quantity of grumous matter escaped. A large-sized drainage tube was sewn in, and removed after ten days. Recovery was uneventful.

The Pembrokeshire Education Authority have awarded a Midwifery Exhibition of £20 to Lucy A. Morris, St. Dogmells.

MEDICAL NEWS IN BRIEF.

The Royal Academy of Medicine in Ireland.

AT a meeting of the Section of State Medicine held on Friday last, the following resolution was adopted :—"That the Section of State Medicine of the Royal Academy of Medicine in Ireland desires to express approval of the suggestion contained in the report of the Viceregal Poor-law Commission to convert the entire Poor-law Medical Service in Ireland into a national service, to be paid by the State, to be entered by a competitive examination, the members of such service to be jointly controlled by the central body and the local bodies, and that the medical profession should have one representative on the central body."

The Ethics of Locum Tenens.

The following resolution was passed at a recent meeting of the Council of the Irish Medical Association :—"The Council of the Irish Medical Association desire to give expression to their very strong views on the inexpediency of members of the above accepting the appointment of locum tenens unless requested to do so by the officer going on leave. The Council are also of opinion that all members of the profession ought to be guided in their conduct, under similar circumstances, by the same rule in ethics."

Man Who Looked for Himself.—Amazing Search with a Lighted Candle.

Councillor Tom Coward related an extraordinary experience at a banquet held at Llangollen recently. He said that he returned home one evening after a particularly busy day, and after his wife retired to rest he remained in the sitting-room reading for some considerable time. He went upstairs with a lighted candle and asked, "Where is Tom?" He declares he heard no answer, and remarked, "It is time he returned." He then retraced his steps downwards, but could not find himself! He finally went to bed, and next morning his wife questioned him as to his strange conduct, and said he stood scratching his head in confusion in the bedroom. He could not account for his behaviour and consulted a medical man, who solved the puzzle by saying that one-half of his brain was dormant while the other half was active. Such a case was not unknown in the medical world.

Suicide of a London Practitioner.

An inquest was held at Swindon on Saturday last on the body of Dr. Robert Perriman Fouracre, aged 72, who left his residence at Tollington Park. London, on Wednesday, and was found dead in bed at a Swindon temperance hotel on the following morning. The evidence showed that he had died as a result of poisoning, a bottle which had contained prussic acid being found in his room, as well as a note saying that no one cared for him, that he was tired of life, and the parish might end it. Dr. Fouracre's son said his father had been depressed, owing to the recent death of his sister. He was in practice up to the time of his death, and was known to have resorted to chloral for insomnia. A verdict of suicide whilst temporarily insane was returned.

PASS LIST.

Royal College of Surgeons, England.

AT a meeting of the Council of the College held on Thursday last, Mr. Henry Morris, President, in the chair, the following successful candidates were admitted Members of the College :—

R. C. Allen, G. F. E. Allison, A. K. Armstrong, C. J. Armstrong-Dash, F. J. Ayre, F. J. Ball, M.D., J. C. Balsara, E. C. P. Barnes, E. C. Barnett, H. B. Billups, M.A., W. R. Bristow, G. T. Burke, Frank Butler, Sydney Carter, C. P. Charles, T. C. A. Cleverton, A. FitzWm. Comyn, B.A., A. B. Coomber, H. B. Corry, B.A., K. K. Dadachanji, K. M. Digby, A. E. Evans, A. C. D. Firth, M.A., H. E. Flint, P. J. Franklin, H. G. Gibson, R. G. Gillies, J. H. Gurley, F. N. S. Hitchcock, H. G. Hobson, W. H. Hodgson, B.A., C. R. Hoskyn, A. J. H. Iles, J. P. Johnson, C. E. M. Jones, B.A., J. E. Jones, T. A. Killby, R. de V. King, H. A. Lash, C. J. Loosely, T. F. Lumb, F. E. McKenty, M.D., L. H. I. Mackenzie, W. C. McMurtry, M.D., D. C. Master, B.A., D. A. H. Moses, W. P. H. Munden, R. D. O'Connor, O. P. N. Pearn, F. E. L. Phillips, J. E. Prentis, H. M. Prins, C. P. Raikes, B.A., G. L. Ranking, B.A., R. J. Reynolds, J. S. Rowlands, M.B., H. C. Samuel, G. N. B. Segastian, Sidney Slade, J. T. Smalley, Charles Speers, F. E. Sprawson, W. R. Square, T. G. Starkey-Smith, R. W. Stephenson, R. W. Stocks, W. H. R. Sutton, B.A., H. H. Taylor, B.A., C. H. B. Thompson, C. B. Ticehurst, B.A., W. F. Todd, St. J. A. M. Tolhurst, B.S., G. S. Totseau, F. T. Turner, F. F. A. Ulrich, M.B., J. A. Venning, B.A., Behdjet Wahby, Harry Wales, T. N. Watt, S. H. West, M.B., H. O. Williams, W. H. Williams, B.A., John Winder.

Diplomas in Public Health were granted, jointly with the Royal College of Physicians, to the following candidates :—Dr. A. G. Banks, Dr. H. G. Bennetts, Mr. W. D. Betenson, Dr. B. Blacklock, Dr. R. B. Ferguson, Capt. J. H. Hugo, D.S.O., I.M.S., Capt. S. P. James, I.M.S., M.D., Major A. E. C. Keble, R.A.M.C., Capt. P. J. Probyn, D.S.O., R.A.M.C., Major O. L. Robinson, R.A.M.C., Dr. A. G. P. Thompson, Capt. A. L. A. Webb, R.A.M.C.

Examiners Appointed.—Mr. Frederic Eve, Surgeon to the London Hospital, was re-elected and Mr. J. Ernest Lane, Surgeon to St. Mary's Hospital, was elected a member of the Court of Examiners.

Diplomas for Women.—A Petition was read from the London School of Medicine for Women in reference to a proposal now before the Council that women should be admitted to the examinations of the College. It was determined to inform the petitioners that the matter is receiving the consideration of the Council.

Army Medical Service.

The following is an official list of the successful candidates at the recent Competitive Examination for the Royal Army Medical Corps, arranged in the order of merit. Seventy-six entered :—

W. K. Beaman, M.R.C.S., L.R.C.P.; C. Cassidy, B.A.Cantab., M.R.C.S.; A. D. Fraser, M.B., B.Ch., Univ.Aberd.; M. P. Leahy, B.A., M.B., B.Ch., Univ.Dub.; F. T. Turner, M.R.C.S., L.R.C.P.; A. I. Fortescue, M.B., B.Ch., Univ.Aberd.; H. G. Gibson, M.R.C.S., L.R.C.P.; J. L. Wood, B.A.Cantab., M.R.C.S.; S. Field, M.R.C.S., L.R.C.P.; R. D. O'Connor, M.R.C.S., L.R.C.P.; D. F. Mackenzie, M.B., B.Ch., Univ.Edin.; J. E. M. Boyd, M.R.C.S., L.R.C.P.; G. Carlisle, M.R.C.S., L.R.C.P.; E. M. Middleton, M.R.C.S., L.R.C.P.; O. R. McEwen, M.R.C.S., L.R.C.P.; J. H. Gurley, M.R.C.S., L.R.C.P.; F. H. M. Chapman, M.R.C.S., L.R.C.P.; A. C. Elliott, B.A., M.B., B.Ch., Univ.Dub.; J. du P. Langrishe, M.B., B.Ch., Univ.Dub.; W. G. Aviss, M.R.C.S., L.R.C.P.; W. B. Purdon, M.B., B.Ch., R.U.I.; H. M. J. Perry, L.R.C.P. and S., I.; J. C. Hart, M.B., B.Ch., R.U.I.; M. O. Wilson, M.B., B.Ch., R.U.I.; T. H. Scott, M.B., B.Ch., Ed.; L. A. A. Andrews, L.R.C.P. and S., I.; G. F. Rudkin, M.R.C.S., L.R.C.P.; V. T. Carruthers, M.B., B.Ch., Ed.; H. W. Farebrother, M.R.C.S., L.R.C.P.; F. Casement, B.A., M.B., B.Ch., Univ.Dub.

Of the foregoing successful candidates, 4 were students of Dublin University; 2 each of Edinburgh and Aberdeen Universities; 2 each of Charing Cross, St. George's, Guy's, St. Bartholomew's, St. Mary's, St. Thomas's, and the London Hospital Medical Schools; 2 each of Queen's College, Cork, and Queen's College, Belfast, and 1 each of Birmingham University and King's College, London.

THE Army Council have decided that administrative medical officers shall in future have administrative medical charge and authority as regards their areas as is now vested in principal medical officers. Administrative medical officers and senior medical officers of the larger stations will, before submission to higher authority, bring such questions to the notice of local commanders, in order that the latter may have an opportunity of expressing their opinions thereon.

NOTICES TO CORRESPONDENTS, &c.

☞ **Correspondents** requiring a reply in this column are particularly requested to make use of a *Distinctive Signature or Initial*, and to avoid the practice of signing themselves "Reader," "Subscriber," "Old Subscriber," &c. Much confusion will be spared by attention to this rule.

Original Articles or Letters intended for publication should be written on one side of the paper only, and must be authenticated with the name and address of the writer, not necessarily for publication but as evidence of identity.

SUBSCRIPTIONS.

Subscriptions may commence at any date, but the two volumes each year begin on January 1st and July 1st respectively. Terms per annum, 21s.; post free at home or abroad. Foreign subscriptions must be paid in advance. For India Messrs. Thacker, Spink and Co., of Calcutta, are our officially-appointed agents. Indian subscriptions are Rs.15.12.

WANTED—A THREEPENNY PIECE.

He was an impecunious, seedy, out-at-the-elbows person, and the doctor, when he prescribed for him, knew better than to expect a fee. "For the inflamed eyes," said the benevolent physician, "dissolve as much boracic acid as you can put on a threepenny piece in half a glass of water." "Thank you, doctor," murmured the patient, turning away. A moment later, however, the door was opened and the patient glided in. "I say, doctor," said he, with an ingratiating smile, "where do I get the threepenny piece?"—*Exchange.*

Dr. H. L. S.-(1). Yes. (2). Yes. (3). We will enquire further, but our impression is that you could not obtain one without great trouble. A surgical instrument-maker might be able to give you information. However, we will enquire.

BRIGHT'S DISEASE.

The discoverer of Bright's disease was Dr. Richard Bright, of Bristol. He was born in 1789, being the third son of Richard Bright, the banker, who died at Ham Green in 1840. His eldest brother, Henry, was member for Bristol from 1820 to 1830. The next brother, Benjamin, became a banker, and his younger brother, Robert, Sheriff in 1852, married Miss Caroline Tyndall, daughter of Thomas Tyndall, of The Fort, Bristol.

Meetings of the Societies, Lectures, &c.

WEDNESDAY, FEBRUARY 13th.

Hunterian Society (London Institution. Finsbury Circus, E.C.). 8.30 p.m.: Paper:—Dr. Langdon Brown: Acetonuria, its Clinical Significance and Treatment.

Dermatological Society of London (11 Chandos Street, Cavendish Square, W.).:—5.15 p.m.: Meeting.

University College (London) Medical Society (Medical Library, University College, Gower Street, W.C.).—8.30 p.m.: Paper —Dr. H. Head: The Grouping of Sensory Impulses. :

Medical Graduates' College and Polyclinic (22 Chenies Street, W.C.).—4 p.m.: Mr. H. L. Barnard: Clinique. (Surgical). 5.15 p.m.: Lecture:—Dr. G. H, Savage: Unsoundness of Mind not always Insanity.

North-East London Post-Graduate College (Tottenham Hospital, N.).—2.30 p.m.: Cliniques:—Dermatological (Dr. Meachen), Ophthalmological (Mr. Brooks), Medical Out-patient (Dr. Whipham).

Central London Throat and Ear Hospital (Gray's Inn Road, W.C.).—5 p.m.: Demonstration:—Dr. J. Atkinson: External Ear.

THURSDAY, FEBRUARY 14th.

Harveian Society of London (Stafford Rooms. Titchborne Street, Edgware Road, W.).—8.30 p.m.: Papers:—Mr. R. Johnson: A Case of Fatal Extravasation of Urine from the Ureter from Ulceration of a Minute Calculus. Dr. T. B. Hyslop: Psychorhythm and Recurrent Psychoses.

Ophthalmological Society of the United Kingdom (11 Chandos Street, Cavendish Square, W.).—8 p.m.: Clinical Meeting. Mr. L. Cooper: Paralysis of the Vertical Movements of the Eyeball. Mr. A. S. Morton: Case of Sclerosis of the Eyeball. Mr. M. L. Hepburn: A Case of Polychoria associated with Chronic Glaucoma. Mr. W. Tay: A Case of Tuberculosis Diagnosed from the Ophthalmoscopic Appearance of the Fundus.

British Gynæcological Society (20 Hanover Square, W.).—8 p.m,: Introductory Address:—The President (Mr. W. D. Spanton). Paper:—Dr. J. Oliver: A Study of Suppuration of the Ovary, with illustrative cases.

Medical Graduates' College and Polyclinic (22 Chenies Street, W.C.).—4 p.m.: Mr. Hutchinson: Clinique. (Surgical). 5.15 p.m.: Lecture:—Mr. M. Morris: The Treatment of Some Common Skin Affections.

North-East London Post-Graduate College (Tottenham Hospital, N.).—2.30 p.m.: Gynæcological Operations (Dr. Giles), Cliniques: Medical (Dr. Whiting), Surgical Out-patient (Mr. Carson). 3 p.m.: Clinique:—Medical In-patient (Dr. Chappel). 4.30 p.m.: Lecture:—Dr. Whiting: Acroparæsthesia (with cases).

St. John's Hospital for Diseases of the Skin (Leicester Square, W.C.).—6 p.m.: Chesterfield Lecture:—Dr. M. Dockrell: The Relation between Cicatrix, Keloid, Scleroderma, and the Treatment of each.

FRIDAY, FEBRUARY 15th.

Society for the Study of Disease in Children (11 Chandos Street, Cavendish Square, W.).—5 p.m.: Clinical Evening for the Exhibition of Cases followed by Discussion. Patients in attendance from 4.30 p.m.

Epidemiological Society (11 Chandos Street, Cavendish Square, W.).—8.30 p.m.: Paper:—Colonel D. Bruce, C.B.: Recent Researches into the Epidemiology of Malta Fever.

Medical Graduates' College and Polyclinic (22 Chenies Street, W.C.).—4 p.m.: Mr. A. Lawson: Clinique. (Eye).

North-East London Post-Graduate College (Tottenham Hospital, N.).—9.30 a.m.: Clinique. Surgical Out-patient (Mr. H. Evans). 2.30 p.m.: Surgical Operations (Mr. Edmunds). Cliniques:—Medical Out-patient (Dr. Auld), Ophthalmological (Mr. Brooks). 3 p.m.: Clinique:—Medical In-patient (Dr. Leslie).

TUESDAY, FEBRUARY 19th.

Therapeutical Society (Apothecaries' Hall, Blackfriars, E.C.). —4.30 p.m.: Ladies' Day and Conversazione. There will be various exhibits and Dr. Crichton will read a Paper upon "The Metric System in Prescribing and Dispensing."

Vacancies.

Leyton Urban District Council.—Medical Officer of Health. Salary £475 per annum. Applications to R. Vincent, Clerk to the Council, Town Hall, Leyton.

Kidderminster Friendly Societies Medical Aid Association.—Qualified Assistant. Salary £150 per annum. Applications to Dr. Martin, 4 Lion Street.

Middlesex Hospital, W.—Resident Medical Officer. Salary £200 per annum, with residence and board in the Hospital. Applications to F. Clare Melhado, Secretary Superintendent.

Guy's Hospital.—Surgeon to the Actinotherapeutic Department. Salary £100 per annum. Applications to the Treasurer, Superintendent's Office, Guy's Hospital, S.E.

Guy's Hospital.—Medical Radiographer. Salary £100 per annum. Applications to the Treasurer, Superintendent's Office, Guy's Hospital, S.E.

Guy's Hospital.—Second Surgical Radiographer. Salary £100 per annum. Applications to the Treasurer, Superintendent's Office, Guy's Hospital, S.E.

King Edward VII. Sanatorium, Midhurst, Sussex.—Junior Assistant Medical Officer. Salary £100 per annum, with board, lodging, and attendance. Applications to the Hon. Secretary, 19 Devonshire Street, Portland Place, London, W.

Glasgow District Asylum, Gartloch, Gartcosh.—Resident Assistant Medical Officer. Salary £125 per annum, with board and lodging. Applications to the Medical Superintendent.

Brecon and Radnor Joint Counties Asylum, Talgarth, R.S.O., Breconshire.—Assistant Medical Officer. Salary £140 per annum, with furnished apartments, board, washing, and attendance. Applications to the Medical Superintendent.

Shillelagh Union.—Medical Officer. Salary £130 per annum and £15 a year as Medical Officer of Health. Applications to J. Hopkins, Clerk of the Union. (See advt.)

Incorporated Dental Hospital of Ireland.—House Surgeon, Assistant House Surgeon, and Extra Assistant Dentists. Applications to W. A. Shea, Registrar. (See advt.)

Appointments.

Higgs, Frederick, W., M.B.Lond., M.R.C.P.Lond., Assistant Physician to the Belgrave Hospital for Children.

Johnstone, Thomas, M.D.Edin., M.R.C.P., Honorary Consulting Physician to the Coronation Hospital, Ilkley.

Lockyer, Cuthbert, M.D., B.S.Lond., F.R.C.S.Eng., M.R.C.P.Lond., Obstetric Physician to Out-patients at the Great Northern Central Hospital and Physician to Out-patients at the British Lying-in Hospital.

Martin, H. C., M.B., B.S.Edin., Assistant Medical Officer at the Newport Borough Asylum, Caerleon, Mon.

McIlroy, A. Louise, M.D.Glasg., Gynæcologist to the Victoria Infirmary, Glasgow.

Births.

Campbell.—On Feb. 5th, at Ruigh-Ard, Inverness, the wife of Robert B. Campbell, M.B., Medical Superintendent, Inverness District Asylum, of a son.

Haughton.—On Feb. 3rd, at Tannachie, Falmouth, wife of J. Welby Haughton, L.R.C.P.I., of a son.

Trotter,—On Feb. 9th, at Holmfirth, Yorkshire, the wife of Robert H. Trotter, M.D., of a daughter.

White.—On Feb. 7th, at Star Hill, Rochester, Kent, the wife of Clement White, M.D., of a daughter.

Woolley.—On Feb. 9th, at 25 Claremont Road, Surbiton, the wife of Edward John Woolley, M.D., of a daughter.

Young.—On Feb. 2nd, at Woolacombe, North Devon, the wife of Thomas Young, M.R.C.S., L.R.C.P., of a daughter.

Marriages.

Goulden—Huyshe.—On Jan. 31st, at the Parish Church, Clyst Hydon, Devon, Herbert Edward Goulden, M.R.C.S., L.R.C.P., D.P.H.Cantab., of Clyst Hydon, only son of Mr. and Mrs. E. B. Goulden, of Emscote, Canterbury, to Ethel Julia, eldest daughter of the late Canon F. J. Huyshe, Vicar of Wimborne, Minster.

Ramsey—Pace.—On Feb. 9th, at St. Margaret's, Westminster, Andrew Maitland Ramsey, M.D., Glasgow, to Elizabeth Margaret Pace, M.D., daughter of the late Thomas Richard Pace.

Woods—Dickinson.—On Feb. 7th, at St. Saviour's Cathedral, Pietermaritzburg, Natal, William James Woods, F.R.C.S., to Mabel Eleanor Kathleen, fourth daughter of C. H. Dickinson, J.P., Ilfracombe.

Death.

Gay.—On Feb. 8th, at 137 Upper Richmond Road, Putney, Elizabeth Gay, widow of the late John Gay, F.R.C.S., aged 82.

HARLEY STREET.—One of the largest Houses in this street to be Sold. Full-sized billiard room on ground floor. Stabling for five horses.—Full particulars of A. B. C., Medical Press and Circular (London Office), 8 Henrietta Street, Covent Garden.

THE MEDICAL PRESS AND CIRCULAR.

"SALUS POPULI SUPREMA LEX."

VOL. CXXXIV. WEDNESDAY, FEBRUARY 20, 1907. No. 8

NOTES AND COMMENTS.

Naval Nurses.

IT is well known that the Admiralty have the question of nursing in the Navy under consideration at the present time, and it is rumoured that the sick-berth attendants are to be turned into a corps whose members are to be as highly trained in sick-nursing as ordinary hospital nurses are, and that a much larger use of female nurses is contemplated for shore work. Deceived, probably, by the equivocal gender of the word "nurse," the news is already being published that every battleship in the Navy will in the future carry a complement of trained female nurses as part of her crew. Advocates of co-education would probably find in such an arrangement a charm which the ordinary person would miss—the softening of the rough sailor's nature, the raising of his moral tone, and the bracing of the nurse's feminine instincts by contact with the virility of the tar. But it is doubtful whether Jack himself would like to be civilised by the presence of women on board, and certainly the cares of the internal economy of the battleship would be increased enormously for the captain and officers. Up to the present a truce has always been granted to matrimony and flirtations on board a man-o'-war, but it is difficult to foretell what might not happen in a three years' commission on some lonely station, and much as there is to be said for women nurses in naval hospitals, and even in hospital ships, it is hardly consonant with common-sense that they should form part of the crew of the fighting units of the fleet.

A Way they have in the Army.

THE nursing sisters in the army are beginning to find for themselves some of the practical difficulties of organisation among those not accustomed to discipline, especially when their exact pigeon-hole in the orderly-room has not been defined by long usage. Consequently there are complaints, and, naturally, frequent references to red tape and sealing wax. When the nurses become imbued with the tastes and habits of the service, however, they will probably find out how to jog along comfortably and how by methods of circumlocution to paralyse the official arm. But the spirit and traditions of a service are not picked up in a day, and in the meantime there are grumbles. At Colchester, for instance, it is said that the nursing sisters are upset because although they are allowed by government 13s. a week for messing, yet they do not see their 13s. and have no control over the way it is invested. The matron sees to all that. Now for food alone, 13s. a week for each of a number of people in a mess is a liberal allowance, and the matron ought to be able to do things very comfortably. If she does not the nurses should form a mess-committee and do their own catering, which is quite a "way they have in the army," and a sensible way too.

Legal or Medical Coroner.

THERE is some strong feeling at Leicester on the subject of a new coroner whom it is proposed to appoint. The same point has been raised over and over again, namely, whether a coroner should be a medical man or a lawyer, and it is solved in many cases by certain individuals combining the two qualifications. Against a man who is both a barrister and a medical man it is impossible to say anything if he has had the necessary experience and is possessed of the requisite personal qualities, but if there is no such candidate and the question lies between two men of equal personal qualifications, one a barrister or solicitor and the other a medical practitioner, which is likely to make the better coroner? The question is almost ludicrous to those who have had much to do with inquests. The function of a coroner being to enquire into the causes of mysterious deaths, it hardly seems worth arguing that a man trained and skilled in the diagnosis of disease is better than a man who knows nothing about life, death, or disease but what he reads in the newspapers. The amount of law required in the execution of the coroner's duty is exceedingly small, in fact almost non-existent if the individual himself has a clear head and sound conception of the principles of evidence. No man is condemned to any punishment as the result of the verdict of a coroner's jury, all that they can do being to find that there is a *prima facie* case requiring further investigation by a magistrate.

Behind the Inquests.

BUT important as is the function of holding inquests, the coroner has the almost more difficult one of deciding entirely on his own responsibility whether in each case reported to him an inquest should be held. Both from the point of view of public safety and from that of public economy, it is highly desirable that a medical man should determine these questions. Unnecessary inquests, and there are plenty of them, are mere waste of time and money, whereas by deciding against an inquest in any case a coroner may be covering up a crime. Only a man well acquainted with disease in all its manifestations is capable of coming to a wise conclusion in circumstances often of great difficulty in which a lawyer is sure to blunder. It is, then, in the quiet day-to-day work that a medical coroner can be of such special value to a town or district, and this point should be impressed on authorities who have the appointing of coroners and wish their work to be done to the greatest benefit to the public.

The Sanatorium Afloat. HAVING had to draw attention from time to time to the objections entertained by people to sanatoriums for the tuberculous being built in their neighbourhood, and considering that this objection increases rather than decreases, we regard it as a remote contingency that at some time in the future it will be impossible to get sites for the purpose—that is, if the present fashion in the treatment of tuberculosis continues to hold its own. It is a comfort, then, to know that there are even better prospects of cure for the consumptive in floating sanatoriums than in those founded on the land, and that an enormous kind of houseboat sanatorium is regarded as the ideal by some folk at least. One of these, writing in the *Scotsman*, claims that from the point of view of primary expense and of general upkeep the floating sanatorium would be more economical, and that if it were moored in Strait of Kyle, between Skye and the mainland, not only would there be no ground rent to pay, but the inestimable advantages of the Highland breezes would be enjoyed. We know the Scots are a hardy race, and no doubt their consumptives can stand a good deal, but we hardly fancy they would get the maximum of good from living on the water level through a winter on the West Coast. But so many startling things have happened in the treatment of consumption that it may turn out that there is more in this suggestion than is immediately apparent.

Sanitation and Surcharge. ZEAL for sanitary administration may at times go hand in hand with forgetfulness of formalities, and as has just happened at Stoke Newington with unfortunate consequences. The district auditor of the Local Government Board has been going through the accounts of the Borough Council of that district, and he finds that through an oversight on the part of the officials, application was not made to the County Council to pay half the salaries of the medical officer of health and sanitary inspectors, which of course should have been done. Moreover, the statutory time-limit, six months, had been exceeded, so that the auditor said he himself had not power to alter the conditions prescribed by the law, namely that the councillors should find the money themselves. Now as Stoke Newington has a pretty energetic organisation in its sanitary department the salary list is a large one, and the sum to be paid at present is the considerable one of £1,162 10s. This works out at £40 a member, and it certainly seems hard lines that the councillors should be saddled with this expense through a technical error. There are surely some loop-holes by which the irregularity can be got over, for sanitary authorities are not likely to be encouraged to increase their staffs when they run the risk of remunerating them out of their private pockets.

Police and Doctor. THE relations of the police and medical men are generally of the happiest character, each having learned the value of the other from experience under conditions of difficulty and danger. But while medical men yield to none in their admiration of the discipline and pluck of the police, it is important for the latter to recognise that a doctor is a man of considerably greater knowledge in matters of life and death than they, and to yield him precedence when such matters are involved. A disgraceful incident lately happened at West Gorton, in which the police not only arrested a would-be suicide in spite of the advice of a medical man who was attending to him, but summoned the latter for obstructing them in the execution of their duty. The medical man was acquitted on a technical point, and so was unable to state the circumstances, but we are glad that his colleagues are taking the matter up, as the medical ideal of the sacredness of life cannot be sacrificed to the rules of any service.

LEADING ARTICLE.

THE CONSCIENTIOUS OBJECTOR AND COMING LEGISLATION.

SINCE Mr. Balfour called the "conscientious objector" into existence a good deal of water has flowed under London Bridge. His new departure was clearly a sop thrown to the small but noisy crew of the anti-vaccinationists. It is even remotely possible that he and his colleagues, being swayed by the influences that appeal to all governments, had some sort of eye to conciliating a section of voters. Be that as it may, the plain outcome of his legislation in that particular direction has been to make the anti-vaccinationists more noisy and clamorous than before. The fact of the matter, it must be admitted, is that the "conscientious objector" has found himself to a great extent thwarted by the difficulties of proving his *locus standi* before the magistrates. So long as human nature exists on its present basis there must inevitably be objectors to any kind of legislative compulsion. In the case of small-pox the government were long ago persuaded that the only way to check the ravages of that terrible malady was to enforce the practice of vaccination. The wisdom of that policy has been amply vindicated by the practical disappearance of a loathsome malady that before the days of vaccination was well-nigh universal. At this time of day, there is no need in the columns of a medical journal to discuss the efficacy of vaccination both as a protective and a preventive agency. The experiences of the London epidemic a few years since proved once again in a most emphatic fashion that the incidence and the mortality of the disease were exaggerated to an extreme degree among that part of the population unprotected by vaccination. All these things are incontrovertible, and, as already said, more than justify compulsory vaccination. Under these circumstances that government would be bold indeed which would accept the responsibility of abandoning a system that has produced such marvellous results. The only comprehensible practical ground for opposition is the fallacy put forward by the anti vaccinationists who say that the diminution of small-pox, a fact that they are compelled to admit, is due not to vaccination, but to isolation and other measures of public health. Much the same line of argument might be used in the fairly analogous instance of the use of antitoxin in diphtheria. The fatality of the disease has been reduced by more than half since the introduction of antitoxin. Yet the antivivisection faddist is loud in his clamour against the introduction of "filthy serum" into the human body. Antitoxin may possibly in the course of time lead to the practical stamping out of diphtheria, just as vaccination has led to that remarkable result in small-pox. The antivivisectionists may say that improved sanitation alone will in the course of time lessen the incidence of diphtheria, but they may be reminded that the disease showed for many years a remarkable and rapid increase before the discovery of antitoxin, and that in the very days when public sanitation according to the anti-vaccinationists was doing away with small-pox, why should diphtheria flourish and small-pox diminish under improved public health administration? Moreover, when science furnishes the appropriate preventive or curative vaccine, or antitoxin, or serum for each specific infection we may hope to limit and ultimately to eradicate scarlatina, measles, whooping cough, and other infectious maladies that show no signs of abating in spite of the vastly improved conditions of modern hygiene. But the faddist is not given to the logical weighing of facts. It is enough for him that the practice of vaccination is in some instances attended by bad results and that it is compulsory. In this particular instance the good of the many has been secured at the expense of the unfortunate few, just as the safety of a country is sometimes paid for by the death of the soldiers in war. Mr. John Burns has announced that he is about to introduce fresh vaccination legislation at an early date, with a view of placing the conscientious objector on the stronger basis afforded by permitting a statutory declaration to take the place of a police court appeal. It is a pity that the Government, in dealing with so important a matter as "compulsory vaccination," have allowed themselves to be forced into any reactionary or false scientific position. With the accusation freely levelled against the medical profession to the effect that they make enormous sums out of public vaccination and are therefore interested parties we are not concerned. A similar attack might be made on any of the liberal professions, as well as a host of commercial and financial interests, and we have no fear that libels of that kind will have the slightest weight with Sir Henry Campbell-Bannerman's Government.

CURRENT TOPICS.

New Lunacy Law in France.

WHILE the lunacy law and administration of this country is being investigated by a Royal Commission, it is interesting to note what is taking place with regard to the corresponding arrangements in France. From time to time during recent years the French law regarding lunatics and the method of their certification has been under review, but no amendment to the old law, which is nearly seventy years old, has yet been made. However, after a long tussle the Chamber has just been induced to pass a bill which if confirmed by the Senate will materially alter the position of the insane. The chief motive that has operated in bringing about the passing of this bill is the need for greater protection of the individual, which, although practically seldom or never improperly infringed, was theoretically liable to be so by the old provisions. Indeed, all that was needed to consign a person to an asylum was a demand by a relative or friend, backed up by one medical certificate, or in the case of violence, an order by a magistrate or police commissary, also supported by one medical certificate. Apart from conspiracy, it is obvious that it was quite possible for genuine error to be committed under these circumstances, and though the superintendent of an asylum had to re-certify the patient at the end of twenty-four hours and again at the end of a fortnight, he would naturally be influenced greatly in his decision by facts alleged in the original certificate. The new law proposes that every lunatic shall have the power of resisting a certificate before a judge, who alone can make an order for reception, and much more thorough medical examination is required. The detention of patients after admission is dealt with on similar lines. Moreover, great changes in the administration and inspection of asylums are to be brought about. As in this country, only to a greater degree, inspection of and medical attention to the insane have been inadequate, but the staff of medical experts in both branches is to be increased. We trust our own Royal Commissioners now sitting will duly observe these points, as any provisions for the greater safeguarding the public from mistaken or improper certification would correspondingly increase confidence in medical men and diminish their liability to be sued by dissatisfied patients.

The Cerebro-Spinal Meningitis Invasion.

THE "spotted fever epidemic," to use its popular name, continues to spread, although it is to be hoped that its appearance in some instances is merely sporadic. The cases in Liverpool are approaching a hundred in number, with a high death-rate. Recently a case was reported in London by the Medical Officer of Health for

Lambeth, who at once removed the patient to hospital and adopted every possible precaution to prevent the spread of the disease. Should this not prove to be a sporadic case the outlook for the metropolis will be one of grave anxiety, when the acute and fatal nature of the malady is taken into consideration. For the next few weeks medical men both in hospital and in private practice will be keenly on the watch for cases of epidemic cerebro-spinal meningitis. As a matter of fact, the disease is readily detected if the medical attendant be not taken unawares A similar remark applies to typhus, a disease that has happily become unknown to the present generation of medical practitioners. Not many years ago a series of fatal cases were for a long time undetected in the Metropolis. There can be little doubt that sporadic cases of cerebro-spinal meningitis in different parts of the kingdom have escaped recognition, as there is great similarity between the different forms of meningitis, and the distinctive rash is absent in the majority of cases. The disease has so far invaded Belfast, Edinburgh, Glasgow, Leith, Lanarkshire, Hawick, Whitburn, Govan, Partick, Kilmarnock, Dunfermline, Chesterfield, Grangemouth, Wolverhampton, Longton, and London. This points to an extremely serious state of affairs, and demands vigilant and united action on the part of public health authorities throughout the kingdom. We are glad to know that the London County Council are about to take the first important protective step, namely to make the disease notifiable.

Poor Law Reform.

It is now stated that the Royal Commission appointed in December 1905 to enquire into the whole subject of the Poor Laws do not expect to complete their labours and report for another two years. The prospects of new legislation so urgently called for seem somewhat remote. No suggestion is made of publication of an interim report, which might enable the Government to deal at once with some of the more pressing questions, such as that of vagrancy. Upon this a Departmental Committee has already reported. Guided by the experience of Continental nations, many of which have worked out practical and successful systems of dealing with the vagrant, the unemployed and the so-called unemployable classes, this Committee had no difficulty in unanimously formulating a scheme to suit our home requirements, compatible with our ideas of freedom, and even respecting our prejudices. Reform of the Poor Laws lies at the root of social progress. Unless such questions are taken in hand and dealt with, the problem of raising the standard of our people, physically, mentally and morally to the level of leading Continental nations must remain unsolved. This is a national and an imperial question. So far as our profession is concerned—no doubt a comparatively personal and minor consideration—improvement in the position of Poor Law Medical Officers could be effected without new legislation. This perhaps may be brought about when the profession learns to combine, and demand that just treatment from the State which is now its due in so many different directions.

Physical Training of Recruits.

An important crusade has been undertaken by Lieutenant-Colonel F. A. Davy, M.D., late R.A.M.C., against the system of physical training imposed on recruits in the Army. As the result of various articles and letters he was asked this month to lecture at the Royal United Service Institution before an audience of officers, many of them gymnastic experts, and an instructive discussion followed the lecture. Colonel Davy is of opinion that the circulating troubles which so commonly develop in soldiers are due to the forced and abnormal position of the chest enjoined on them by drill-sergeants, and he holds that the physical efficiency of the soldier would be infinitely greater if he were allowed to adopt a natural position on parade and on the march. Revolutionary as this doctrine is of all that has been taught in the army since time immemorial, there are few of Colonel Davy's civilian colleagues who will not be found heartily to agree with him, and in spite of the opposition of the bulk of the military officers who spoke after the lecture, we fancy that drastic changes are likely to be introduced into the system before long. The *United Service Gazette* is strongly on the side of reform, and it is understood that the War Office contemplate abolishing the present methods in favour of some modification of the Swedish system. Commander Watson, Superintendent of Physical Training in the Royal Navy, is convinced of the superiority of the Swedish methods, and he made the interesting suggestion that the physical training of recruits should be handed over to and form part of the duty of medical officers. Considering that medical men are instructed in physiology and with departures from the normal in the structure and health of man, it would seem the merest platitude to assert that the physical development of the soldier should be placed under their supervision, but it is a sign of grace that the fact should be admitted, and indeed urged, by such an officer as Commander Watson.

Another "Marvellous" Cure for Cancer.

The way in which the public precipitate themselves into the pits dug by the hands of the quack would be comical in the extreme were it not overshadowed by the ever-present shadow of suffering and death. The man in the street runs after every will-o'-the-wisp of quackery that flits through the columns of his daily paper, while he is apt to neglect the crowd of silent, conscientious, highly trained and highly qualified medical practitioners for whose professional fitness the State has become voucher. If only the unqualified pretender can spend sufficient money in advertising, he is certain to attract a large following of dupes. He may sell a rheumatic ring, or a cure for alcoholism, or electric socks, or give himself out as able to cure locomotor ataxy, chronic kidney disease, or any other incurable malady—there is no claim too fantastic and extravagant for his purpose. The latest heaven-born healers are two brothers named

Evans, small farmers near Cardigan. They treat all kinds of diseases, including cancer, with some sort of liquid obtained entirely from herbs, which is painted over the affected spot and a dressing of fresh garden leaves, bruised by being rolled under a bottle, is then applied. Crowds of patients have placed themselves under the care of these two men, who are said to be possessed by a spirit of "deep religious fervour." The whole affair is a couple of centuries behind the times. It should be absolutely impossible under any system of government jealous of the welfare of its citizens.

University Schemes in Ireland.

As was anticipated, opinion hostile to Mr. Bryce's university schemes is rapidly finding expression in Ireland. Trinity College will offer an unyielding opposition. The Fellows and Professors have met, and with unanimous voice, have decided to take every means in their power to prevent the absorption of the College in any new university. In this attitude there is no doubt that the College authorities will have the full support of the body of graduates. It is claimed that there is no shadow of excuse for depriving an ancient, honourable, and successful corporation of its privileges and prestige. No one has heard as yet of a University with three hundred years of laborious work behind it being deposed to the position of a mere college. In the provincial centres of education the scheme is also exciting oppositon. Public opinion in Cork is strongly roused, and the local press is urgent against the absorption of the Queen's College in any university situated in Dublin. For Belfast, President Hamilton's evidence may be taken as representative, and he is strongly hostile. Public bodies in Galway are protesting against any degradation of the local Queen's College to a lower position than its sisters in Belfast and Cork, and indeed this proposed degradation seems a very gratuitous slight on an institution doing excellent work.

No Provision for Payment of Medical Fees.

The common attitude of the nation with regard to medical services seems to be that they are whenever possible to be secured gratuitously. In this way certificates of sickness are obtained wholesale at hospitals by friendly societies, by Council schools and by other bodies or individuals. That important and indispensable legal document, the certificate of death, was to be provided gratuitously by the medical practitioner, no matter what amount of money may be involved indirectly in his attestation. With a profound faith in the careless benevolence of the profession, the framers of the Midwives' Act made it imperative upon the midwife under certain circumstances to call in the assistance of a registered medical practitioner, but at the same time neglected to provide for the payment of such practitioner. It can hardly be wondered at if the medical practitioner is not particularly anxious to attend cases. The matter has been up in one form and another all over the country, and no decisive step has yet been taken. The question is one that cannot be postponed indefinitely, and should preferably be settled by Parliament.

Interest in the Public Health.

THERE are not wanting signs of an awakening interest on the part of the public in matters affecting the health of the community. In some cases the interest is sadly uninstructed, and can hardly produce good results. It is, however, the duty of medical men to act as guides in sanitary matters, and to encourage in every way the formation of a healthy and enlightened public opinion. We are glad, therefore, to note the establishment in Ireland of a Woman's National Health Association, for the express purpose of arousing women "to a sense of their responsibility regarding the public health, and to spread the knowledge of what may be done in every home and by every householder to guard against disease, and to promote the upbringing of a healthy and vigorous race." Among the problems to which the Association intends to devote itself are those of consumption and infant mortality, of pure milk supply, and of the hygiene of primary schools. It is a comprehensive programme, and well worthy of the exertions of the women of Ireland. We notice that among the methods to be adopted are lectures and addresses by medical men. The president of the Association is Her Excellency the Countess of Aberdeen, whose business ability is known to equal her philanthropic zeal. We wish the Association every success in the work it has taken in hand.

PERSONAL.

DR. MORGAN J. REES, M.D., D.P.H., has been unanimously elected Medical Officer of the Aberdare Urban Council at a salary of £500 a year.

DR. THOMAS H. A. VALENTINE, Deputy Health Officer, Wellington, New Zealand, has been promoted Inspector-General of Hospitals.

THE Senate of Cambridge University has paid Principal Macalister the compliment of asking him to continue to represent that University on the General Medical Council.

DR. GLYNN, Professor of Medicine in the University of Liverpool and Consulting Physician to the Royal Infirmary, has been elected a member of the Council of the Royal College of Physicians, London.

A PRESIDENT'S Dinner of the Royal Medical Society was held on February 7th in the Royal Medical Society's building, Edinburgh. The guest of the evening was Professor Osler, M.D., LL.D., F.R.S., Regius Professor of Medicine, Oxford. Dr. Drennan presided.

DR. C. E. BEEVOR will give the presidential address at the annual general meeting of the Neurological Society to-morrow. His subject will be "The Distribution of the Arteries Supplying the Human Brain."

DR. T. L. OWENS has been appointed Surgeon and Admiralty Agent at Holyhead.

A CLINICAL LECTURE
ON
HYDRONEPHROSIS, WITH NOTES OF AN EXTREME CASE OF THAT DISEASE.

By WILLIAM ALEXANDER, M.D., F.R.C.S.,

Lecturer on Clinical Surgery, Liverpool University, and Honorary Surgeon, Royal Southern Hospital, Liverpool.

Gentlemen,—We have had several cases of hydronephrosis in our wards lately, and a very rare and extreme example was discharged from hospital a few days ago. You all know that hydronephrosis means a collection of more or less watery urine in the dilated pelvis of the kidney, caused by a partial obstruction to the natural flow of urine through some part of the urinary passages. In all these cases of hydronephrosis the obstruction is a partial as well as a gradually increasing and an intermittent obstruction. Complete unyielding obstruction of a ureter by a ligature produces, not hydronephrosis, but atrophy of the corresponding kidney. The uncompromising pressure of the excreted urine upon the secreting cells and tubes of the kidney destroys their vitality. In the same way intermittent pressure on the skin of the foot produces a thickening of the epirdermis, but the constant pressure of a splint destroys the skin and produces an ulcer. Hence some surgeons, when a ureter is necessarily or accidentally injured in performing abdominal hysterectomy, tie it, knowing that that kidney will atrophy and that the opposite kidney will enlarge and so be able to overtake the work of two. The causes of obstruction, and consequently of hydronephrosis, may be either temporary or permanent. Amongst the temporary causes are kinking of urethra in movable kidney, small calculi that block the ureter and afterwards pass on into the bladder, renal calculi that sometimes block up the entrance to the ureter and cause hydronephrosis, and at other times fall back into the pelvis of the kidney. Uretritis and phosphatic deposits may narrow the ureter so that it does not drain the kidney efficiently. Both conditions pass away through subsidence of the inflammation or alteration in the composition of the urine, when the temporary hydronephrosis completely and permanently disappears. Hence a tumour in the loin, oval, smooth and mobile, that enlarges and diminishes from day to day coincident with a scanty or a profuse flow of urine, is sure to be a hydronephrosis. Permanent hydronephrosis may be produced by an impacted stone in any part of the urethral tract, by gradually increasing organic stricture of the ureter, by pressure of a tumour on any part of the course of the ureter, by a tumour of the bladder closing the lower orifice of the ureter, by stricture of the urethra, but this last cause rarely produces much hydronephrosis, because, although the dilatation of the pelvis exists, other and more serious inflammatory changes also take place and make the hydronephrosis secondary to the septic condition

I shall now briefly describe to you a case of recent hydronephrosis which some of you saw a short time ago, and I hope you remember the course and treatment of the disease.

Mrs. S——, æt. 39, married, the mother of five children, the eldest 17, youngest 18 months. Commenced to menstruate three weeks ago for the first time since her parturition 18 months ago. Felt "run down" after the strain of menstruation was added to the previous strain of nursing of her baby for 18 months, but, except for some degree of languor and weakness, she was quite well. A fortnight ago she went to bed as well as usual, and soon went to sleep. In the middle of the night she was awakened by a severe pain in her left side, so acute that her husband brought in a doctor at once, who administered morphia. When the effects of the morphia had passed off, the pain was less acute, and had become a "dull aching." She vomited occasionally, but never in any great quantity. Micturition for the past fortnight had been sometimes very frequent, say every ten minutes; at other times not at all frequent.

On examination the abdominal wall was loose and flaccid, moved freely, and was quite flat. On the left side a clearly-defined, distinct, small oval tumour could be seen and felt, having its long axis pointing downwards and inwards. It moved slightly on respiration, was tender to touch, could be pushed upwards under ribs, but not downwards. Fluctuation could not be elicited. The percussion note was clear all over the swelling except on the outer side, where the note was dull. Urine, clear acid, sp. gravity 1,030, contained a trace of albumen. An X-ray photograph of the renal uretral and vesical regions did not reveal anything further. After a week's rest in bed, as the tumour was enlarging and the pain increasing and the entire quantity of urine passed per diem only 8 to 10 ozs., we cut down upon the kidney in the loin, found its pelvis distended with fluid, and the entire kidney much enlarged, but otherwise quite healthy. The pelvis was opened through the cortex, the fluid allowed to escape, and a long whip catheter was passed down the ureter without meeting any palpable obstruction. With the fingers and needle, and both by exploration and palpation, the kidney was thoroughly examined, but no stone or gravel could be found. A piece of gauze was placed in the kidney wound to drain in the right direction the blood and urine that flowed for some hours from the incision. Next day the patient was found to have passed by the urethra 8 ozs. of blood-stained urine, and the dressings were soaked with blood-stained fluid. The passage of blood by the urethra was of great importance, as it showed us that the ureter was clear. Next day the blood had disappeared from the urine that had been passed naturally, but the dressings were still saturated with a watery fluid, mostly urine. In ten days the urine ceased to come by the wound; at the end of a month she was discharged, so well that she said she felt "a different woman."

It is difficult to say with certainty what the cause of obstruction in this case was, but probably it was a stone which we moved on by the passage of the catheter down the urethra. No stone was, however, seen or heard of, and we may have cured the case by relieving tension, by draining the kidney for a few days, but there is no doubt we cured the disease permanently. We do not always obtain such good results from drainage. Some of you may remember a young girl whom I operated on several months ago, and where the old symptoms of pain and distress recurred whenever the wound in the loin healed up. This patient required to wear a small drainage tube in the fistula opening, which I believe she is wearing still. She was told that if the wearing of the tube was too irksome, to come back and we would relieve her by a further operation. She has not yet come back to claim my promise. What we could do should she become dissatisfied with her state would be the same treatment that we dealt out to a case in the private ward about six months ago. A hydronephrosis had been relieved by drainage, but the loin tube was necessary, as distressing symptoms, such as fever, vomiting, pain, etc., occurred whenever it was removed. The continual use of the drainage tube became an intolerable nuisance to the patient, both on sentimental as well as on practical grounds. The cause of obstruction in her case was probably due to broad ligament inflammation of so old a date that an operation to free the ureter did not look either safe or practical. We ascertained by segregation that the right kidney was active and efficient, and we removed the hydronephrotic kidney completely. It was a mere shell. The patient is now an active, healthy woman.

In some cases aspiration of the tumour is practised, the relief of tension being sufficient to allow of the flow of urine through an orifice that greater tension will close. If carefully performed, the operation of aspiration is a safe one, but generally temporary in its relief. My experience has led me to drain from the loin as a surer way out of the difficulty, and one quite as safe.

Confident in aseptic surgery, we may now explore the ureters externally from the kidney to the bladder, or may catheterise the ureters from above or below, and thus cure the disease without any mutilation of the patient, but still in many cases the removal of a dilated and comparatively useless kidney will be the best practical treatment.

I will now call your attention to a monstrosity of a hydronephrosis, a case that, though rare, is not unique, and I will relate it as it appeared to the different observers who had to do with it.

L. E., æt. 23, a young woman, who had always lived with her parents, began to be troubled with a distension of the lower abdomen, accompanied by pain in the left ovarian region, that gradually became intolerable. It was diagnosed as an ovarian tumour by several medical men who examined her, and she entered a woman's hospital to have an ovarian tumour removed. An incision was made, a sac was exposed, the tumour tapped, and clear fluid was drawn off. The sac was so adherent everywhere that an attempt at enucleating was soon desisted from. Whether the tumour was drained or not I cannot tell; at any rate a fistulous opening developed just below the umbilicus. The patient was sent back to bed, and the urinous nature of the escaping fluid was soon placed beyond doubt by the usual urinary effluvia. She was sent home shortly after, and you may imagine the condition of the girl during the year she passed before coming to us, a nuisance to herself and everybody near her, her clothes constantly moist with urine and with foul odour clinging to her person, making her an outcast from society. Her doctor then asked me to take a case of urinary fistula into hospital, and when she was admitted I was surprised to find the fistulous opening half-way between the umbilicus and the pubis, instead of in the loin, where for some reason I expected it to be. The girl was fairly well nourished and in good health, had been relieved of pain by the previous operation, but was in greater distress since by the constant flow of urine. A catheter passed into the bladder seemed to pass up nearly to the fistulous opening, and in the absence of any definite history, we thought at first that the distress was due to leakage from the bladder, and had been caused by wounding that viscus in the operation of ovariotomy a year ago. I enlarged the fistulous opening so as to be able to introduce my forefinger into the cavity, and found an immense potential space that burrowed beneath the viscera away up to the left hypochondrium, down into the pelvis, towards the left to the flanks, and a little way to the right beyond the median line. The bladder was quite normal, and had no connection with the sac. I cut down upon the left renal region, and found no kidney, but only the sac of the hydronephrosis, which I opened with my finger introduced in the median line, and passed a large rubber tube from the middle line through the flank, so as to thoroughly drain the sac from the side and keep the patient drier than she had been. It was evident that we had to do with an enormous hydronephrosis, the sac of which occupied the whole of the left side of the abdomen, and that a left kidney still existed somewhere sufficient to secrete a large quantity of urine and to keep the patient during all her life most odorous and uncomfortable. We did not find a kidney in the usual place, and close questioning of the patient revealed a history of some urinary trouble for many years, incontinence, frequent micturition, and dysuria. Catheterism and radiography did not enable us to discover any calculus anywhere in the urinary tract. Digital examination failed to discover an pelvic disease of any kind. Segregation of the urine showed that the right kidney was secreting plenty of healthy urine, but that not a drop came from the left kidney. It was now plain that the patient had a good, active, sound right kidney that we could depend upon in case of need, and that our course was to find the left kidney, open up the pelvis, and try to establish communication with the bladder, or, failing this, to remove the kidney.

On June 15th, 1906, I made the usual oblique incision between the last rib and the iliac crest which is considered necessary to expose the left kidney. When I reached the circumrenal fat, I explored as far up as the spleen and the diaphragm, and down to the crest of the ilium, but no kidney could be felt, nor anything resembling a kidney. The wound was then extended downwards and inwards, so as to expose the brim of the pelvis. An elongated nodulated structure was now found lying over the sacro-iliac synchondrosis and dipping down into the pelvis. This at first looked like a colon contracted on small scybalæ. Further examination, however, revealed the colon itself distinct from this nodulated structure that lay behind. On carefully isolating the latter, it turned out to be the kidney we were seeking, displaced and deformed. From the pelvis of this kidney the sac extended down into the pelvis close to the bladder. This part of the sac was explored by finger, probe, and catheter, but no opening could be found leading into the bladder, and no course was left but to remove the kidney. The renal vessels were tied, the opening in the sac made by cutting across the pelvis of the kidney was closed by suture, and the large abdominal wound brought together by deep-buried catgut sutures and superficial silkworm-gut skin sutures. The old median abdominal sinus was left open to allow of the discharge of mucus that would for some time be formed in the sac.

The kidney, though deformed and much elongated in shape, was healthy, but we must remember that for the past twelve months it was working under normal conditions and had probably recovered its health and vigour, both of structure and function.

Whilst preparing this lecture for the press at the beginning of 1907, I wrote to the patient asking her to describe her present condition. She says she is quite well and very comfortable. About "half-a-thimbleful" of mucus comes from the old sinus below the umbilicus. She passes urine naturally, and is never wet or offensive.

It seems a very serious mistake to take a hydronephrosis for an ovarian tumour, a mistake that caused the patient much pain and distress for a long period. But let us, with the key to the case in our hands, project ourselves back into the position of the original observers. They saw a young girl, with a gradually increasing fluid tumour in the left ovarian region, that produced a good deal of pain and was accompanied by some dysuria, and it is most likely we would all of us, under the circumstances, have diagnosed ovarian disease, as they did. Had we segregated the urine, we would have found that no urine came from the left side, and we might even then have only diagnosed that the tumour pressed on the ureter so as to prevent the flow from the kidney. But who would have thought of segregating the urine which passed apparently naturally and in full quantity, the opposite kidney having at an early stage of the disease undertaken double work. The congenitally displaced kidney that lay in the pelvis instead of the hypochondrium was the point in the case that rendered correct diagnosis improbable. Had the kidney been in its normal position, its enlargement would at once have been referred to the true cause, and operation would have relieved the patient long before. As the tumour grew larger and larger, the probability of its ovarian nature increased still more and more, although perhaps the shape of the tumour might have put on the right track anyone who has had experience of such cases. But who has had such experience? We who are present at this lecture have had a very exceptional experience, one that few have had, and I hope that the memory of this case will be so vivid that when a similar case occurs to some of us we will be able to diagnose it. Had any of the previous observers thought of such a diagnosis, he could have proved it by segregation of the flow of urine into the bladder, examination of the aspirated fluid, etc. We who have studied this case and have had our efforts directed to it for some weeks will always think of it, and Nature will not be able to deceive us so readily as others who have not seen, but have only heard of extreme cases of hydronephrosis. The chances are, however, that none of us will see such a case again.

The case also shows the danger of jumping at conclusions or of judging from appearances, and the advantage of always considering seriously everything, no matter how improbable, that a tumour under consideration might be, before coming to a final conclusion. If this were systematically done, many errors of diagnosis would be avoided that only occur from want of thought.

NOTE.—*A Clinical Lecture by a well-known teacher appears in each number of this journal. The lecture for next week's issue will be by J. B. Story, M.D., F.R.C.S.I., Surgeon to the Royal Victoria Eye and Ear Hospital, Ophthalmic Surgeon to Dr. Steevens' Hospital, Dublin, on "The Treatment of Concomitant Convergent Strabismus."*

ORIGINAL PAPERS.

ACID INTOXICATION FOLLOWING GENERAL ANÆSTHESIA.

By ROBERT CAMPBELL, M.B.R.U.I., F.R.C.S.Eng.,
Assistant Surgeon, Royal Victoria Hospital, Belfast, etc., etc.

Most surgeons must, I think, have been impressed by the idea that, in certain cases of death following the performance of an operation, the fatal result has been largely attributable to the action of the anæsthetic It is only within the last year or so, however, that sufficient evidence has been forthcoming to clearly prove that the danger of a general anæsthetic does not end with the return of the patient to consciousness, and that death may ensue from its action alone as much as several days after the administration. So far back as 1852 Casper called attention to this subject, and different Continental surgeons have referred to it at intervals. To Dr. Leonard Guthrie, of London, belongs the credit of first directing the attention of the profession at home to this very important matter. In 1894 he published in the *Lancet* a communication entitled "Some Fatal After-Effects of Chloroform in Children." In this paper he gave details of ten cases which had come under his own observation, and described most clearly the symptoms and post-mortem appearances. But he did not succeed in convincing the profession of the truth of his observations. The writer of a leading article, which appeared subsequently in the *Lancet*, endeavoured to show that death in Dr. Guthrie's cases might with greater probability have been ascribed to the absorption of carbolic acid or the occurrence of fat embolism. In 1903 Dr. Guthrie returned to the subject. In the meantime one complicating factor, carbolic acid, had been almost entirely eliminated from operative surgery. His second paper appeared in the *Lancet* of July, 1903, and was entitled "On Fatal Effects of Chloroform in Children suffering from a Peculiar Form of Fatty Liver." Therein he gave a description of four additional cases, one of these being an adult. This paper was received with much less scepticism than the first, and in 1904 Mr. Stiles and Dr. McDonald, of Edinburgh, communicated to the Society for the Study of Diseases of Children a very valuable and exhaustive *résumé* of the whole subject, giving a minute description of the symptoms and post-mortem appearances presented by three cases which had occurred in their practice. Previous to the publication of this paper I had met with four cases of death following operation which had puzzled me greatly. I did not, however, suspect the anæsthetic. In two of these cases septic tuberculous sinuses were present, and I not unnaturally ascribed the deaths to septicæmia. The other two were certified as meningitis. Unfortunately, during the past year I have had three other cases following operation on children under chloroform. The clinical symptoms presented by these patients and the post-mortem appearances placed the cause of death beyond any reasonable doubt, and convinced me that delayed chloroform poisoning is a dread reality. I shall briefly describe these cases.

CASE I.—F. B., a boy æt. 4 years, was admitted to the Children's Hospital suffering from an inguinal hernia. So far as I could ascertain he was in fair health. He was, however, inclined to be constipated, and had recently shown a tendency to drowsiness, of which his school teacher had complained. This I naturally ascribed to the foul atmosphere of our national schools. The evening of the day of operation he vomited several times. The vomiting continued during the night, but next morning there was nothing in his condition to excite alarm. The vomiting recurred during the day, and early the following morning became severe. The child by this time was evidently very ill. The pulse had risen to 160, while the temperature was normal. He was seen by one of my colleagues, who was of opinion that his symptoms pointed to intestinal obstruction. Some hours later I saw him. He had then recovered to some extent; the vomiting had not recurred, but the pulse was over 120, and the child was restless and excited. Examination of the abdomen revealed nothing. Being very sceptical on the subject of delayed chloroform poisoning, and afraid that a piece of intestine might have slipped down and become strangulated, I unfortunately resolved to open up the wound. To do this a little chloroform was given. Nothing, however, was found wrong with the wound, which was sutured again. The child soon afterwards began to vomit profusely, became drowsy, then comatose, and died in the evening fifty hours after operation.

As this was the first case of death following operation for the radical cure of hernia in 362 cases operated on in the Children's Hospital, I was very anxious to ascertain the cause of the fatality. I accordingly got Professor Symmers to perform a post-mortem examination.

When the abdomen was opened the liver at once attracted our attention by its bright yellow colour—it might be described as canary-coloured. Not a trace of red liver tissue was to be seen either on the surface or in the sections. The tissue was friable and the cut surfaces had a greasy appearance. It was plain to the naked eye that the liver was a mass of fat. The cortices of the kidneys were in section pale grey.

Six weeks after this catastrophe two other cases occurred.

CASE II.—R. C. M., æt. 5 years, was operated on for a cleft involving both the hard and the soft palate. The operation was easily performed, and only occupied thirty-five minutes. During the night the patient was very sick and restless. The following morning he was still vomiting at intervals, but his appearance was good. During the afternoon he became drowsy. The drowsiness gradually increased, and slight cyanosis appeared. Eventually he became comatose, with Cheyne-Stokes respiration. The temperature rose towards the end to 102°. With my previous experience I recognised the condition, and ordered the administration of a purgative and the injection into the bowel of a large quantity of solution of bicarbonate of soda, and a hypodermic of strychnine, but he died thirty-eight hours after operation. Post-mortem examination revealed exactly the same condition of liver as in the previous case.

CASE III.—R. H., æt. 6 years, was operated on for the radical cure of hernia. He vomited at intervals during the night, and next morning suddenly took convulsions which affected the whole body and recurred at short intervals for half an hour. After the convulsions ceased he remained in a semi-comatose condition. Purgatives and rectal injections of solution of bicarbonate of soda were given, but the coma deepened, the respirations became Cheyne-Stokes in character, and he died thirty hours after operation.

The post-mortem examination showed the same intense fatty degeneration of the liver as in the other two cases. These three cases appear to be typical instances of so-called delayed chloroform poisoning. The fact that three deaths from this cause have occurred within a space of two months makes the subject one worthy of our most earnest consideration, and of immense importance not only to operating surgeons, but also to all who have occasion to use general anæsthetics. It is for this reason that I have brought them under your notice, and I hope that my sad experience may have the effect of forcibly directing your attention to what I am firmly convinced is a very real danger attendant on the administration of chloroform, especially to children.

I shall now proceed to discuss some points a little more in detail.

I.—*The Symptoms* naturally vary somewhat in different cases. It will have been noticed, for instance, that one child had convulsions and another became cyanosed, while in the third case neither of these was present. The symptom complex has been given by Bevan and Favill as follows:

(1) *Vomiting.*—This is generally profuse and prolonged, and tends to become coffee-ground in appearance.

(2) *Restlessness.*—Sometimes an expression of excitement or fear is observed.

(3) *Rapid Pulse.*—A rate of 140–160 is common.

(4) *Delirium.*

(5) *Convulsions.*

(6) *Coma.*

(7) *Cheyne-Stokes Respiration or "Air Hunger."*

(8) *Cyanosis.*

(9) *Icterus* is generally slight.

(10) *Smell of Acetone* from the breath and urine.

The resemblance of these symptoms to those of acute yellow atrophy of the liver is at once apparent; but in chloroform poisoning jaundice, if present, is slight, and there are no hæmorrhages. The absence of these may be due to the more rapid course of the chloroform cases.

II.—*The Post-mortem Appearances* are very characteristic. Indeed, Dr. Guthrie asserts that in no other condition except possibly phosphorus poisoning has he seen the same condition of liver. Stiles and McDonald, however, have observed it in some children who have died without an anæsthetic having been given. The liver is normal in size, or slightly enlarged, firm in consistence, and uniformly yellow The other organs are not affected to the same degree, but fatty degeneration of the cortices of the kidneys is plainly seen, and fatty changes are also observed in the muscles, especially those of the heart.

III.—*The Cause of Fatty Degeneration.*—That chloroform alone is capable of producing these changes has been conclusively proved. Experiments conducted on rabbits have shown that chloroform cannot be administered to them for an hour without causing death, preceded by symptoms of poisoning, and post mortem fatty degeneration of the liver is always found. Stiles and McDonald record some interesting observations on this point. A number of rabbits were anæsthetised with ether and a portion of the liver of each removed. After recovery from the operation the abdomen was again opened under chloroform and another portion removed. A few days later the rabbits were killed, and the livers examined. These were always found to have undergone marked fatty degeneration subsequent to the administration of chloroform.

If we admit, as I think we must, that deaths such as I have described are due to delayed chloroform poisoning, we have next to consider whether in these cases there may be some impurity in the chloroform, or some error in its administration, or some idiosyncrasy on the part of the patient.

I.—*The Chloroform.*—I have always used chloroform made from ethyl alcohol. Although I have no evidence to show that there was any impurity of the chloroform used in these fatal cases, still I have noticed that particular bottles of chloroform have had the effect of producing intense vomiting in every patient for whom they have been used. For instance, two private patients anæsthetised from the same bottle vomited most profusely after the performance of simple operations, viz., excision of varicose veins and radical cure of hernia. It might be contended that the varicose vein case was a prolonged operation and consequently a large amount of chloroform was used, but the radical cure of hernia lasted only twenty minutes, and yet this patient, a little girl of seven years, exhibited most marked symptoms of poisoning, profuse and prolonged vomiting, restlessness, and pulse rate of 160. Fortunately, after the administration of a purgative and large quantities of solution of bicarbonate of soda, she rapidly improved, and in forty-eight hours after operation was quite well.

The anæsthetist informed me that two patients of another surgeon for whom the same chloroform was used suffered in the same way.

After one of my fatal cases I endeavoured to get the chloroform that was left analysed, but unfortunately there was not sufficient for the purpose. We have no proof, therefore, that impure chloroform plays any important part in these cases.

II—*The Administration.*—It has been asserted by a French writer, who recently published an article on the subject, that poisoning is always the result of administering the chloroform vapour in a too highly concentrated state. He says that a 2 per cent. mixture of chloroform with air is the limit of safety. If this is so, and if chloroform is to be continued as a general anæsthetic, resort must be had to some other method of administration than those in general use. Some experiments published recently in the *Lancet* show that with a Junker's Inhaler 15 per cent. of chloroform vapour can be given off. The percentage certainly must vary greatly according to the quantity of chloroform in the bottle, the vigour with which the bellows is used, and the temperature of the operating room. As regards my own cases I have some reason to believe that possibly too high a percentage of chloroform vapour was given. On the occasion of two of the fatalities there were a great number of operations to be done, and the administration may have been unconsciously hurried. Certainly subsequent investigation showed that the amount of chloroform used was much above the usual quantity. It is also worthy of note that all the patients chloroformed on the same day were attacked with profuse vomiting quite as severe as in the fatal cases, but tending gradually to pass off. Most observers are agreed that the duration of the operation and the amount of chloroform used are important factors in the production of post-anæsthetic vomiting. All surgeons must have remarked how severe and persistent the vomiting is likely to be after a tedious operation such as the removal of tuberculous glands from the neck. But the operations in my fatal cases were all short, the longest occupying only thirty-five minutes. This fact directs one's attention to the patient, and makes us ask if there is not in fatal cases a susceptibility to the action of chloroform.

III.—*The Patient's Condition.*—The majority of cases of chloroform poisoning have occurred in children. Those suffering from rickets and infantile paralysis appear to be specially liable to it. Dr. Guthrie is of opinion that in all fatal cases there is a pre-existing fatty degeneration of the liver and that the chloroform merely acts as the "last straw." Mr. Stiles and Dr. McDonald, on the other hand, take the view that all the post-mortem changes may be produced by the chloroform alone, and quote in support of this the extensive degenerations produced in animals. In this connection I am indebted to Dr. Rankin for calling my attention to an important point. It is known to experimental physiologists that herbivorous animals take chloroform very badly. An analysis of the cases of death in children after CHCl shows that the most dangerous age is between four and five years. Now this is the period of life when children of the working class get the least proteid in their diet. They are fed mainly on bread and jam and potatoes and gravy. They are practically speaking herbivorous animals. Infants, on the other hand, who are fed entirely on milk, take chloroform very well. They very often do not vomit at all. Their food contains a large amount of proteid. This observation fits in with what has been noted about the susceptibility of ricketty children.

I have also some reason to believe that there is some hereditary cause which predisposes to chloroform poisoning. For instance, in one of my cases I learned from the father afterwards that two other children of the same family had died in much the same way without any anæsthetic having been used. These cases were certified by the family doctor as meningitis. In another case of unexpected death which I had some years ago I discovered subsequently that a brother of the child had died in exactly the same way the day after being operated on by one of my colleagues. These two cases certainly point to some family weakness.

Although most of the cases hitherto described have occurred in children, the condition is by no means confined to them. Within the past few months I have noticed in the medical journals two cases of acute yellow atrophy of the liver following confinement. In both these cases $CHCl_3$ had been freely used.

The influence of the anæsthetic in septic cases was most graphically shown in a recent paper giving the results of operation for suppurative appendicitis at the Edinburgh Hospital for Children. When $CHCl_3$ was the anæsthetic used; only four cases out of nineteen recovered. When ether was substituted the proportion of deaths and recoveries was almost reversed.

In discussing the question of susceptibility to chloroform poisoning Bevan and Favill give the following as predisposing causes:—

1. Age—children.
2. Diabetes.
3. Previous recent anæsthesias.
4. Septic infection.
5. Dead fœtus in utero.
6. Gangrenous mass in the abdominal cavity, *e.g.* a strangulated ovarian cyst.
7. Exhaustion due to hæmorrhage.
8. Starvation.
9. Carcinoma.
10. Lesions resulting in fatty degeneration, *e.g.* infantile paralysis.
11. Chronic disease of the liver and kidneys.

The frequency of deaths from chloroform poisoning is certainly much greater than has been hitherto suspected. In going over the operations in the Children's Hospital for some years back I find there have been thirteen deaths which, in the light of our present knowledge, may be fairly regarded as due to this cause. Seven of these have been under my own care, including the three which I have described in detail. The other four were an osteotomy, a tenotomy and myotomy for spastic paraplegia, and two cases of tuberculous sinuses. As the last two were septic, I concluded at the time that the scraping of the sinuses had disseminated the septic matter. Consequently I certified them as septicæmia. In the other cases the vomiting followed by coma suggested meningitis. In one of these, however, a post-mortem examination of the brain made by Dr. Lorrain Smith failed to confirm this view. Unfortunately we had not permission to make a complete examination of the body.

In addition to fourteen cases recorded by Dr. Guthrie, six or seven have been described by Mr. Stiles, and in the *Lancet* of November, 1906, Telford and Falconer give a detailed account of three fatal cases occurring in a few months at the Manchester Children's Hospital, viz., a case of cleft palate, a case of radical cure of inguinal hernia, and a case of osteotomy of the femur. That these cases of fatal chloroform poisoning are not confined to, although much more common in, children has been shown by Ballin, who has collected nine cases of so-called acute yellow atrophy of the liver following operations under chloroform in adults. Bevan and Favill have also collected twenty-seven cases of different ages.

How the Poisonous Effects are produced is still unexplained. It has been noted that after the administration of chloroform or ether acetone and diacetic acid appear in the urine, and it has consequently been suggested that these are the active poisons. Those of us who are in the habit of treating children are familiar with the fact that periodic vomiting is often associated with the presence of acetone and diacetic acid in the urine, and I think that it is quite probable that some deaths occur from this acid intoxication apart from the administration of an anæsthetic. In examining the urine of children before operation I have sometimes found diacetic acid in considerable quantities present. In three cases of infantile paralysis operated on recently it was present in large amount, and these are cases which are admitted to be very prone to chloroform poisoning. It is therefore possible that fatal cases are the result of the production of acetone and diacetic acid by chloroform in patients already suffering from acid intoxication. A long series of observations carried out at the Hospital for Sick Children in Edinburgh goes to show that symptoms of poisoning are most frequently observed in the cases in which an examination of the urine has revealed the presence of acetone and diacetic acid. On the other hand, these substances may be merely the associates of a poisonous material not yet recognised. The intense fatty degeneration of the liver must almost entirely destroy its power to prevent the passage through it of poisonous material carried from the intestines by the portal vein. I believe it has been shown that when large quantities of acetone are administered to animals no poisonous symptoms supervene. The subject is therefore one which requires still further investigation.

Treatment.

1. *Prophylactic.*—Adopting the view that acetone and diacetic acid play a part in the production of the symptoms, the detection of these in the urine of a patient requiring an operation should contra-indicate the use of chloroform. Ether should be employed instead. It is true that the administration of ether also leads to the production of these substances; but it is contended that the kidneys not being damaged in their excreting power by ether, rapid elimination of them takes place. With a view of neutralising the diacetic acid, alkalies should be administered before operation. Bicarbonate of soda in half-drachm doses may be employed for this purpose.

2. *Curative.*—Many patients who exhibit the preliminary symptoms in a marked degree recover, *e.g.* the little girl operated on for hernia whose case I have mentioned. When the symptoms arise a good purgative should at once be given. An attempt should also be made to restore the alkalinity of the blood. For this purpose copious rectal injections of bicarbonate of soda should be given. Dr. Thomas Houston informs me that lactate of soda is a much more efficient preparation for the purpose. In addition, hypodermics of strychnine are also advisable.

A consideration of the subject forces us to the conclusion that ether is a much safer anæsthetic than chloroform, both as regards the immediate and the remote mortality, and that it should always be employed as a general anæsthetic unless there is a definite contra-indication to its use.

REPORT UPON

CEREBRO-SPINAL MENINGITIS IN GLASGOW.

By A. K. CHALMERS, M.D. Glasg., D.P.H. Cantab.
Medical Officer of Health for Glasgow, &c., &c.

The recognition of this disease recently in Belfast and an increase in the numbers notified in Glasgow during the month of January have concentrated public attention on its movements and make some short statement of its present position desirable.

In the memorandum which was presented to the Glasgow Health Committee in May of last year in support of the suggestion that it should be included within the Notification Act, attention was drawn to the circumstance that many of the leading symptoms of the disease were closely allied clinically to certain other diseases, especially of the central nervous system, and also pneumonial, but that in certain cases a distinction could be drawn by the recovery of a micro-organism known by the name of its discoverer, "Weichselbaum." It was also noted, however, that the organisms might escape detection, especially in the later stages of the disease.

Before dealing, therefore, with the cases notified, it may clear away some misconception if we inquire whether any changes are discoverable in the group of diseases of the nervous system with which this particular form may most readily, by reason of its symptoms, become included. And for this purpose the most reliable source of information is a record of the deaths which have been attributed to one or other of these forms during recent years.

The groups here distinguished are—(1) cerebro-spinal meningitis (cerebro-spinal fever), (2) meningitis—inflammation of the brain, etc., and (3) tubercular meningitis.

TABLE I.

Glasgow, 1901–6.—Statement of Deaths Certified under the respective Groupings.

	1901	1902	1903	1904	1905	1906
(1) Cerebro - spinal meningitis (C.S. fever)	1	—	—	—	—	147
(2) Meningitis (simple) inflammation of the brain	438	414	411	388	363	329
(3) Tubercular meningitis	237	244	240	260	237	307
	676	658	651	648	600	783

The most prominent feature of this table is the evidence it contains that during 1906 fatal diseases referable to the central nervous system exceeded by 136 the average of the preceding years.

This results from an increase of 63 under "tubercular meningitis," and 147 ascribed to cerebro-spinal fever, against which must be placed a reduction of 74 from simple meningitis.

It is important to follow these changes a little more closely. Age plays an important part in determining susceptibility to meningeal affections, and a short statement of the relative prevalence at three age-periods will serve to explain why the subsequent inquiry is confined to ages under twenty.

In the year 1906 the deaths ascribed to the tubercular and non-tubercular forms of meningitis (excluding cerebro-spinal fever) at ages 0–5 numbered 449; at ages 5–20, 144; and at ages 20–60, 39.

Again, at ages 0–5 and 5–20 the numbers attributed to tubercular meningitis exceeded in this year the average number formerly registered, and at both of these age-periods the numbers attributed to simple meningitis are lower, with one exception, viz., 1905.

At the age period 20–60 the number of deaths attributed to both forms were 32, 39 and 39, and may therefore be excluded from further consideration.

Now we may follow the record into 1906, and restrict our inquiry into the deaths occurring under 20. For the present we shall exclude cerebro-spinal fever, meningitis, inflammation of brain, etc.

TABLE II.

Deaths Registered as due to Meningitis—Inflammation of Brain, etc., Ages 0–5.

Months.	Total Deaths, 1901–5.	Average Number Monthly.	1905	Departure from Average.
January	117	23	31	—
February	102	20	31	—
March	124	25	20	—
April	138	28	27	—
May	132	26	32	—
June	125	25	29	—
July	133	27	5	22
August	152	30	7	23
September	117	23	18	5
October	114	23	14	9
November	98	20	8	12
December	106	21	9	12
	1,458			83

On running down the line of figures under 1906 two facts are apparent. A change which is scarcely a natural one began in July. The shrinkage which then occurs has no parallel in former years. During 1901–5 the deaths occurring monthly were fairly uniform throughout the year, being on an average 123 in the first six months and 120 in the second. In 1906, on the other hand, 170 deaths are attributed to meningitis during January to June, and only 61 in July to December. The increase in the first half of the year is quite as striking as the shrinking in the latter half, but its significance differs.

Ages 5–20.—It will be sufficient here to reproduce only the half-yearly figures:—

Months.	Total Deaths, 1901–5.	Average Number Monthly.	1906.	Difference.
January to June	195	39	44	+5
July to December	146	30	20	−10
	341	69	64	−5

The departure from the average is still marked here, but less pronounced in view of the smaller number of deaths occurring.

Tubercular Meningitis.—It has already been shown that the number of deaths attributed to tubercular meningitis had increased during 1906. Again, therefore, it becomes desirable to discover during what part of the year this increase occurred, and we must follow a line of investigation similar to that adopted in Table II. in dealing with simple meningitis. This has, therefore, been done in the following table:—

TABLE III.

Deaths Registered as due to Tubercular Meningitis. Ages 0–5.

Months.	Total Deaths, 1901–5.	Average Number Monthly.	1906.	Departure from Average
January	66	13	15	—
February	74	15	13	—
March	76	15	16	—
April	95	19	14	—
May	83	17	15	—
June	62	12	12	—
		—91	—85	
July	79	16	21	5
August	64	13	25	12
September	60	12	21	9
October	73	15	18	3
November	56	11	21	10
December	68	14	27	13
		—81	—133	
	856	172	218	52

If we take as our basis for comparison the average number of deaths occurring in each of the half-years 1901–05 we find some tendency towards a decrease in the incidence of the disease during the months of January to June, but an increase from July to December. This difference is shown in 85 deaths in all being recorded in the first half of 1906 as against 91 in the corresponding portion of 1901–05, while from July to December the deaths attributed to it in 1906 number 133 as against 81 in previous years.

Ages 5–20.—Following again the shortened form adopted in dealing with the deaths from simple meningitis at these ages, the following statement of deaths may be made :—

Months.	Total Deaths, 1901–05.	Average Number Monthly.	1906.
January to June	171	34	35
July to December	151	30	45
	—	—	—
	322	64	80

Can we, then, from these figures form any concrete conception of the movement of meningeal disease in the period under review. We have seen that a fairly uniform incidence and seasonal distribution is maintained until the beginning of 1906, when already in the early months of that year an increasing prevalence is reflected in the deaths which for the first six months are attributed to ordinary meningitis. Deaths due to the tubercular variety of the disease are meanwhile uninfluenced, but in the second half of the year both undergo a change, which is without parallel in the previous periods. Deaths ascribed to simple meningitis decrease, while those from the tubercular variety increase. What circumstance aided in producing this change in nomenclature ? During the late spring months of 1906 attention had been directed to the recognition of a few cases of true cerebro-spinal fever, and in May the Hospitals Committee authorised the issue of a circular to medical practitioners, asking whether other cases of the disease had come under their notice. After the requisite procedure, the disease was made notifiable in August.

The questions now to be answered concern the actual proportion of cerebro-spinal fever in the total volume of meningeal affections. Apart from actual demonstration of the fact by post-mortem examination, I know of no circumstance which suggests that tubercular diseases, meningeal or otherwise, are increasing. Does the excess of deaths attributed to this form of meningitis in the later months of 1906 cover some which are true cerebro-spinal fever, and what proportion of both may be ascribed to simple change in nomenclature ? Neither of these questions can be satisfactorily answered at the moment, but they both indicate a need for the greatest care in scrutinising the deaths which are being attributed to the epidemic form of the disease. It has been said that we are still groping our way towards a true clinical picture of the disease, and that bacterial verification is sometimes impossible, even when the disease is present. Bearing this in mind, we may examine the cases which have been registered since the spring of last year.

It is convenient as well as instructive to consider them in groups, which will distinguish between those treated in the fever hospitals and those treated as home or in the general hospitals.

CEREBRO-SPINAL FEVER.

Cases Registered during 1906.	Total.	Bacterially Verified.	Not Verified.	Not Cerebro-Spinal Fever.
In fever hospitals ..	110	65	28	17
At home or elsewhere ..	103	22	77	4
	—	—	—	—
	213	87	105	21
Deaths—				
In fever hospitals ..	72	47	20	5
At home or elsewhere ..	76	18	56	2
	—	—	—	—
	148	65	76	7

The fatality of the Disease.—It is from this point of view that the "non-verified" case acquires its true significance. Of 105 cases belonging to this category 76 died, which is equal to a fatality rate of 72 percent. and the proportion of fatal cases scarcely varies whether we take it on the hospital or home deaths separately. And on comparing both with the fatal cases among the bacterially verified, the fatality rate corresponds almost accurately with that of the hospital cases, but falls short of that obtaining among the "home" cases, where the fatality rate is 82 per cent. Save, therefore, for the larger proportion of cases, not cerebro-spinal fever, occurring among the hospital group (seventeen in all, of which three were pneumonia and four tubercular meningitis), the inference from both is that we are dealing with a peculiarly fatal form of meningitis, and that it is being recognised without as well as within the hospital.

In dealing with the cases registered during January we may adopt the same classification, but cannot attach to the various groups the same rigid interpretation, as many are still under treatment.

JANUARY, 1907.—CASES REGISTERED AS CEREBRO-SPINAL FEVER.

Cases.	Total.	Verified.	Not Verified.	Not Cerebro-Spinal Fever.
In fever hospital ..	57	34	8	15
At home or elsewhere	50	11	37	2
	—	—	—	—
	107	45	45	17
Deaths.				
In hospital ..	23	18	—	5
At home or elsewhere	32	8	22	2
	—	—	—	—
	55	26	22	7

Death rates calculated on either the verified or unverified groups would seem to indicate a considerable reduction in the fatality—51 and 49 respectively—but at the moment any such inference would be unwarranted for the reason just stated.

Distribution of the Disease.—From the foregoing it will be seen that the cases registered during January show a considerable increase. This began in the second week of the year, since which the weekly numbers registered have been respectively 32, 28, and 28 for the three weeks ended February 2nd. While isolated cases in most wards are of occasional occurrence, the numbers tend to concentrate in the wards towards the eastern and north-eastern portions of the city and in some districts of the south side.

Age Distribution.—The age distribution of the cases follows in a general way what has already been referred to as characteristic of meningeal diseases in general—that is, about 56 per cent. are occurring among children under five years of age, 21 per cent. at ages 5–10, and 11 per cent. at ages 10–20.

Regarding the method by which the infection is conveyed, nothing of a definite character can be said. Multiple cases in households have been observed, but they have mostly been so closely related in date of onset as to suggest simultaneous infection. One of the most suggestive circumstances observed has been the occurrence of a considerable number of cases among breast-fed infants who had no known association with any family suffering from the disease. It was one of the older theories held concerning cerebro-spinal fever that infection reached the central nervous system along the nerve tracks, and the increasing prevalence of the disease during January may have some relation (through depressed vitality and the natural resistance to disease) to the somewhat exceptionally low temperatures which characterised the weeks ending December 29th and January 26th. Whether any definite relation to this can be finally established remains to be seen, but the association suggests that the utmost care should be taken to guard young children against the variations of temperature, and especially the low temperatures through which we are presently passing.

This, together with a rigid observance of absolute cleanliness of everything which may be placed in the mouths of young children, whether for food or other reasons, are suggested by the facts which have come under notice.

In households where cases occur it should be remembered that discharges from the mouth, nose, and ears have been associated with the occurrence of the disease in former outbreaks elsewhere.

EYE AND EAR SYMPTOMS IN CEREBRO-SPINAL MENINGITIS.

By CECIL SHAW, M.D.

(Surgeon to the Belfast Ophthalmic Hospital.)

These symptoms are found to vary greatly in different epidemics, often giving a peculiar type to an epidemic. They are of importance both in diagnosis and prognosis.

Eye Symptoms.—Conjunctivitis is an early sign in 60 per cent. of the cases; generally seen in first day or two.

The Cornea is frequently affected, becoming steamy and infiltrated. Often it clears completely, but it may become ulcerated.

The Pupils may be dilated, contracted, or unequal; there is frequently some photophobia in the early stages.

Iritis, Choroiditis, and Optic Neuritis may occur, together or separately. The two latter are serious as regards the prognosis for sight, for there is apt to be exudation into the vitreous, which becomes organised, drags on the retina and causes its detachment, and eventually destroys sight. Often there is no neuritis, but congestion of the retinal vessels. On the whole, optic neuritis is not so marked a symptom as in tubercular meningitis.

Orbital Cellulitis has been seen occasionally.

Paralyses of the third, fourth, sixth, and first division of the fifth nerve are not uncommon. There is a good description of what I believe to be such a case in *La Clinique Ophthalmologique* for 1901 (p. 225). The case, a lady, æt. 25, was seen in October, 1900, in Nantes; she gave a history of an acute illness in England three months before; violent headache, vomiting, temperature 104°, delirium for fifteen days, and stiffness of the neck, with complete paralysis of all the eye muscles except the external recti, and defective sight. All symptoms passed off except those in the eye, which persisted when seen. The eyes were then turned out by the unopposed action of the external recti, and vision was very poor, the fundus being hidden by a grey exudation. In some months the muscles recovered and vision improved, but remained only 1/15.

The Ear Symptoms are often marked. In the United Kingdom 12 per cent. of the children in institutions for the deaf and dumb are there as a result of meningitis, and no doubt some, though, perhaps, only a few of these, have been cases of cerebro-spinal meningitis. But in Jacksonville, U.S.A., institution, 14 per cent of the cases were the result of cerebro-spinal meningitis alone.

At Oberfrank, in Germany, with a population of 55,000, no less than fifty-eight cases were admitted to the institution for deaf and dumb in two years, as the result of this disease. Moos states that 59 per cent. of all his cases became deaf; and in several epidemics the majority of cases have suffered similarly. According to Knapp and Moos the deafness generally appears in the first or second week. It is generally complete and permanent, being due to inflammatory changes in the nucleus or trunk of the nerve, or in the labyrinth. According to Von Ziemssen, suppurative disease of the middle ear may appear about the twenty-fifth day, and may be complicated by mastoid disease.

The following case which I saw in consultation with Drs. Calwell and McCaul illustrates several of the points noted above.

The patient, a lad, æt. 13, became ill on January 25th, and on the third day suffered from vomiting and vertigo. That night he was found to be deaf. When I saw him on the fourth day he could hear nothing but the shrill sound of a Galton's whistle held close to his ear. The membranæ tympani were apparently normal on both sides, and as far as could be made out, there was almost complete nerve deafness. Blisters were applied over the mastoid on both sides, but no change has taken place, and the deafness seems, if anything, more complete. On the fourth day of his disease, when I saw him first, there was a little injection of the conjunctiva in the left eye, and on the seventh day, when I saw him again, this had increased to slight chemosis; the cornea was steamy and infiltrated, the pupil dilated, and there was a little string of pus running from the iris to the lens. A swab from the conjunctival sac failed to yield the meningococcus. A week later, on the fourteenth day, the conjunctiva was less swollen, the cornea nearly quite clear, the pupil widely dilated, with a thick mass of yellow exudate at its centre, apparently resting on the lens, and there was slight hypopyon. There was no perception of light, and the tension was - 1. The right eye remained normal. I have not been able to go out again since, but hear from Dr. Calwell that the boy goes on well, and can now see a candle at two feet with the left eye. Considering the way in which the cornea has cleared, I should be slow to give up hope of considerable improvement in the sight. The prognosis as regards hearing is very bad. As regards the differential diagnosis, the symptoms in connection with the eye and ear which would point most strongly to cerebro-spinal meningitis in a suspicious case would be an early conjunctivitis, an irregularity in the size of the pupils, steaminess of the cornea, iritis, with or without hypopyon, exudation in the vitreous, and sudden deafness.

CLINICAL RECORDS.

CASE OF GENERAL FŒTAL DROPSY.

By JAMES DUNLOP, M.B., C.M.

(Formerly Assistant Physician to the Glasgow Royal Infirmary).

This is an extremely rare condition, and has been given a number of different names. Hippocrates is supposed to have seen a case and described it as a fleshy fœtus (fœtus carnosus), but a definite case was first described in the seventeenth century. It is not even mentioned in any of the midwifery books in my possession, except Spiegelberg, and it was only when I got Dr. Ballantyne's book on "Ante-natal Pathology and the Diseases of the Fœtus" that I got any definite information about this interesting case.

I shall first give the history of the mother, Mrs. L., æt. 31. Has been married for three years. First child, a fine healthy girl, is æt. 2 years and 1 month, and never required any medicinal treatment. Four or five months after this birth she began to menstruate, but suckled the child for eight months, when she again became pregnant and ceased nursing. Second child was born at the eighth month, on March 10th, 1906; it had been dead for several days and was desquamating. In June, 1906, she again became pregnant for the third time, and felt life about November 1st. At this time she had an attack of influenza, but soon got over it and was in good health both before and after this attack. Fœtal movements were weaker during November, but she felt them distinctly up to the day before labour began. On December 7th, about 5 a.m., he had a slight red discharge, but no pain. In the evening slight pains began and continued all night; the child was born rather unexpectedly about 7.35 a.m. on December 8th. The pains were slight and not lasting long. It was a breech presentation, and nurse tied the cord, but fœtus was quite dead. On my arrival she called my attention to the peculiar swollen condition of the fœtus. It was a male, and resembled a case of acute Bright's disease, with general anasarca, with pitting on pressure. There was no desquamation and no emphysema of skin, but a true dropsy. The skin was smooth, pinky in colour, and showed a number of fine dilated capillaries. The arm was almost translucent on holding it up to the light. The eyelids were so œdematous that the pupils could not be seen when the attempt was made. The abdomen was distended with ascitic fluid and the splenal cavities were also dull to percussion. The scrotum was greatly distended. The weight of fœtus was not ascertained, but it was obviously larger and heavier than a usual six months' fœtus. The placenta was retained and found to be adherent and had to be stripped off by the hand introduced into uterus; it was large, pale and œdematous. Nurse stated that the liq. amnii was not very abundant; it was clear and had no smell. The mother made an excellent recovery. She is a healthy-looking woman, and has no kidney or heart affection, and no specific history. Her husband is a very healthy-looking man. As I have already said, this is an extremely rare disease, and I have never seen a case of it till now, and have never met any one who has had a similar case. I showed the specimen at the Obstetrical Society meeting, but none of the members had seen a case like it. Dr. Ballantyne, of Edinburgh, says in his book on "Ante-natal Pathology" that he has had the rare fortune to examine 11 cases of this disease, and remarks that he is now far less confident as to its pathology than he was after examining his first case, and the *usual clinical history may be summarised as follows:—*

Mother advanced in child-bearing period—over 30. Multiparous as a rule; large number of pregnacies as a rule. Health often bad; previous obstetric history bad.

Father's health—absence of specific history.

Symptomatology of the pregnacy.

Often terminated prematurely; mother's health seldom good; maternal dropsy; unusual degree of abdominal distension from large fœtus and placenta and abundant liq. amnii; fœtal movements feeble.

Third Stage difficult; large dropsical placenta; uterine inertia; rapid and favourable puerperium; weight and measurements of fœtus larger than normal; a general or local œdema; serous fluid oozes out; skin red, livid or pinkish; fluid in pleural pericardial and peritoneal sacs; ascitic fluid may be green, brown or clear; hydrocele or hydrocephalus. Placenta: large, soft, pale; cord thick and œdematous. Hydramnios. Causes of "general fœtal dropsy" looked for in three directions: (1) Morbid state of mother's health; alcoholism, hydræmia, nephritis during pregnacy. (2) A pathological condition of father, as anæmia, syphilis, etc. (3) A pathological condition of fœtus; closure of F. Ovale; cystic kidneys; leukæmic blood. Some have combined 1 and 3 as the cause. Some (Clay) thought placenta at fault, due to maternal syphilis or maternal nephritis, etc. The pathogenesis is very obscure, and needs further investigation.

Antenatal treatment suggested.

$KClO_3$. Fe. and Potass. Strychnini, and proper dieting.

If endometritis treat it: During labour may be difficulty from large fœtus; after labour danger from exhaustion, hæmorrhage and sepsis; hence careful use of antiseptics is necessary.

THE OUT-PATIENTS' ROOM.

KING'S COLLEGE HOSPITAL.

Gluteal Abscess due to Foreign Body.

By Peyton Beale, F.R.C.S.

Amongst the out-patients was a man, æt. 40, complaining of a hard and very painful swelling in the left gluteal region about in a position corresponding to the great sacro-sciatic notch. The history was that he had noticed pain in his pelvis about eighteen months previously, and that the pain had gradually spread downwards towards the buttocks; for the last fortnight only had the pain in this latter situation been severe. On examination there was found to be a swelling about the size of a tangerine orange apparently situated beneath the gluteus maximus and corresponding to the position of the great sacro-sciatic foramen. The skin over the swelling was very red and brawny, and surrounded by an area of œdema. It was obvious that the swelling was an abscess, but as the patient absolutely refused to have anything done to it on that day, a hot carbolic fomentation was applied and the man advised to come up two days later on a Saturday to have the abscess opened. He stated that if it were done on Saturday afternoon he would be able to rest that night and on Sunday. When he appeared on the Saturday there was a soft spot, showing that the abscess was pointing. With the usual preparations, it was opened, and the main cavity was found to be beneath the gluteus maximus, and possibly partly beneath the medius. On inserting a probe no track could be found extending either towards the rectum or through the sciatic foramen into the pelvis. On pressing the walls of the abscess to squeeze out the contents, a solid body was suddenly extruded; when this was washed it was found to be a much-swollen whole pearl barley seed. The cavity was washed out with lotion and a small gauze drain inserted. Mr. Beale said that there was no doubt about the pearl barley seed being the foreign body which was the cause of the abscess; the question was: Where had it come from? The most reasonable explanation was that it had come from the rectum, perforating its wall and forming a peri-rectal abscess which had burrowed. This, however, was extremely unlikely, for such abscesses invariably followed the line of the rectum and pointed as ischio-rectal abscesses. The unlikely but at the same time probable cause of the trouble was that the patient had, months ago, suffered from an attack of appendicitis, the pearl barley seed having been a foreign body within the appendix. Of this attack, however, there was really no definite history to be obtained beyond the fact that about eighteen months previously the patient had suffered from severe abdominal pain of about a week's duration. Mr. Beale was inclined to believe that the patient had really had acute appendicitis with a localised abscess into which the seed had passed, and had then made its way down behind the peritoneum into the pelvis, passed through the great sacro-sciatic foramen accompanied by pus, which had then pointed in the gluteal region.

OPERATING THEATRES.

CHILDREN'S HOSPITAL, PADDINGTON GREEN.

Operation for Ruptured Liver.—Mr. Arthur Edmunds operated on a child, æt. 7, who had been admitted three days previously with the following history: The patient had been hanging on at the back of a cart by his hands and had slipped, falling prone into the roadway; he was picked up and taken home not much the worse for his accident, and subsequently, some hours afterwards, brought to the hospital. The child was slightly collapsed, but there was nothing in his condition to suggest need for any immediate operation. In view, however, of possible future developments he was admitted to the ward for observation. His condition for two days remained about the same. There was no rise of temperature, no distension of the abdomen, no melæna, and nothing to indicate injury to the thorax or its contents; his liver dulness was normal. Mr. Edmunds was called to him late on the third night after admission, and found that his condition was becoming grave. The child was pale, his respirations a little hurried, his pulse quickened. His abdomen moved normally, was only slightly tender, but it was beginning to become distended, and his liver dulness was absent; otherwise percussion of the abdomen showed nothing abnormal. The train of symptoms, Mr. Edmunds said, presented one or two difficulties from the standpoint of diagnosis. The two great abdominal accidents, hæmorrhage, rupture of the bowel, and peritonitis, had to be considered. The accident might have produced either. The mobility of the abdomen was against peritonitis, but the loss of liver dulness was highly suggestive of some perforation of the bowel; this symptom was one to which a varying degree of importance was ascribed. It was certainly true that loss of liver dulness does not necessarily imply free gas in the peritoneum, but when the liver dulness disappeared under observation, its diagnostic significance was much greater. It indicated either free gas in the peritoneum, or some dislocation or distension of the colon. The child's condition was, on the whole, suggestive of hæmorrhage. It was, however, quite obvious that the condition was not clearing up under expectant treatment, and that laparotomy was inevitable. The abdomen was opened accordingly through the right rectus, this site being chosen on account of the loss of liver dulness. On incising the peritoneum, there was a little free serum, but obviously no peritonitis. On separating the coils of the intestine, free blood was found, therefore the spleen was rapidly examined and found to be intact. The anterior surface of the liver was also seen to be normal, but on passing the hand down into the right hypochondrium there was a furious gush of blood. A transverse incision was quickly carried through all the structures of the abdominal wall at right angles to the original opening, and a long roll of gauze packed as quickly as possible into the corner of the abdomen from which the blood seemed to be coming. This arrested hæmorrhage temporarily, so that Mr. Edmunds was enabled to clear the field of operation and investigate the exact state of affairs. An examination was made of the other organs of the abdomen, but nothing abnormal was found. It was obvious, Mr. Edmunds pointed out, that there was a tear in the liver towards its posterior surface, the liver being partially torn from its attachments to the diaphragm. On removing the packing this opinion was confirmed, and the hæmorrhage was arrested by firm packing into the right hypochondrium between the liver and the diaphragm. The point of interest was, Mr. Edmunds remarked, the long time which elapsed between the accident and the onset of grave symptoms. In arterial hæmorrhage the blood pressure is sufficient to overcome a very considerable resistance to the extravasation of blood, but in venous hæmorrhage very slight pressure will temporarily arrest the bleeding. In rupture of the spleen, for example, one has seen a series of attacks of hæmorrhage following slight movements; as long as the patient is kept perfectly still no hæmorrhage occurs; but the slightest movement relieves the bleeding spot of the pressure of the adjacent viscera and re-starts the hæmorrhage. In the present case, no doubt, the liver had been in contact with the posterior abdominal wall, and had automatically checked the hæmorrhage by its own weight; some movement had apparently caused the liver to fall away from this position and re-started the hæmorrhage. It was probable, he thought, that the displacement of the liver was the cause of the loss of liver dulness. The wound had to be left open and the packing was removed on the third day, and no hæmorrhage followed. The wound ultimately healed, and the boy is now well. He has a hernia over the incision, but it causes him no trouble, and it can well be left for treatment later.

TRANSACTIONS OF SOCIETIES.

OPHTHALMOLOGICAL SOCIETY OF THE UNITED KINGDOM.

MEETING HELD THURSDAY, FEBRUARY 14TH, 1907.

R. W. DOYNE, F.R.C.S., Vice-President, in the Chair.

THE evening was devoted to the discussion of Clinical cases.

Mr. **LUDFORD COOPER** showed a case of Paralysis of the vertical movements of both eyes. The patient was a man in whom there was complete paralysis of the vertical movements of both eyes, which had come on suddenly and for which no explanation could be found.

Mr. **J. H. FISHER** had seen two similar cases, one in a girl, who was found one morning unconscious, with this paralysis. She recovered consciousness rapidly, but the paralysis persisted for a long time. The explanation he then gave was an embolism of one of the small arteries of the Corpus Quadrigeminum. The other case showed hemianopic pupil reaction, without a hemianopic field, a condition never before recorded, and *post mortem* a diffuse growth of the Lamina Quadrigemina was found.

Mr. **A. STANFORD MORTON** showed a case of a man, æt. 54, who, two years previously received a steel foreign body in his right eye. The sight of this was immediately affected. About a month later the sight of the left began to fail, and within three months was almost completely blind. Now the right eye showed typical siderosis, with atrophy of the nerve. The left eye showed a similar condition of the disc, the atrophy being of the post-neuritic type; there was marked arterial sclerosis in both eyes. The left pupil showed the Argyll-Robertson reaction. No sign of central nervous disease could be found.

Mr. **MALCOLM L. HEPBURN** showed a case of a man æt. 61, with polychoria associated with chronic glaucoma. The sight of the right eye had become dim recently, though for the last three years he had noticed coloured rings round the lamps; he had had no pain. The left eye was normal in every respect. The right eye showed an unusual appearance of the iris which he stated had been present from birth. There was a complete pupil placed down and in, which reacted to light, while the part between the pupil and the periphery was made up of 5 triangular-shaped bands of pigmented iris tissue, with their bases towards the angle. These bands enclosed clear spaces through any of which the details of the fundus could be plainly seen. In addition to these bands an almost complete circular stump of pigmented tissue was visible at the angle of the anterior chamber, in which the bases of the different bands were lost. The patient stated that the pupil used to be in the centre of the eyeball, but of late years it had gradually come to occupy its present position. The fundus showed glaucomatous cupping of the disc. The case was interesting from a developmental point of view, and two explanations were possible. One that the iris was originally complete, and by subsequent atrophy, as the result of inflammatory action or otherwise, had partially disappeared. The other was a faulty development, which was difficult to understand, since the pupil was perfectly formed. Mr. Treacher Collins suggested as a possible explanation the failure of the formation of some of the loops of vessels which go to form the iris.

Mr. **WAREN TAY** showed a drawing of an eye from a case of tuberculosis, which was only diagnosed after an ophthalmoscopic examination had been made. This occurred 22 years ago. He showed this in order to disprove the statement of an eminent physician who stated that this had never been done.

Mr. J. H. **TOMLINSON** showed a retinoscopy longarm to facilitate the practice of retinoscopy in children.

Mr. **HALLIBURTON MCMULLEN** showed a case of detachment of the retina cured by scleral punctures.

Other cases were shown by Messrs. G. W. Thompson and G. H. Pooley.

ROYAL ACADEMY OF MEDICINE IN IRELAND.

SECTION OF ANATOMY AND PHYSIOLOGY.

MEETING HELD FRIDAY, JANUARY 25TH, 1907.

The President, A. F. **DIXON**, M.B., in the Chair.

THE MUSCULATURE OF THE VILLI.

MR. F. O'B. ELLISON (introduced by the President) presented a note on the above. He pointed out that the villi of the dog are club-shaped, not pointed or cylindrical, as is generally described, and as is the case in the cat. This club-shaped extremity contains a large quantity of smooth muscle which is not connected with the muscularis mucosæ. The latter consists of three layers—outer longitudinal, middle circular, and inner longitudinal. The fibres derived from the muscularis mucosæ in the cat pass round the glands of Lieberkühn, and form a sort of sphincter for the latter. A number of microscopic sections of villi were shown in illustration of the points indicated, and one of the specimens showed compound villi.

Professor W. H. **THOMPSON** said that the appearance of round spaces with transverse sections of muscle in the first section shown would come to some of them as a revelation of the amount of muscle that could be present in villi. When the specimen first turned up he thought these were engorged capillaries filled with blood, but careful examination would convince anyone that this was not so, and they would find undoubted evidence that they were muscle fibres. He had shown the section to certain examiners in London; at first they said they were blood capillaries, but they afterwards agreed that such was not the case. Further facts that Mr. Ellison had made out made it exceedingly probable that there was far more muscle in the villi than came up from the muscularis mucosæ. If so, it would make the working of the villi a mechanical process about which there would not be very much mystery. The investigation, however was not complete.

The **PRESIDENT** expressed the hope that research in the same direction would be continued. It was probable that as much difference would be found between the specimens shown and the villi of the human subject as there was between those of the cat and dog.

THE ESTIMATION OF UREA IN URINE, AND THE ESTIMATION OF HYDROXYBUTYRIC ACID IN URINE.

Mr. **WM. CALDWELL** (introduced by the President) read a paper on the above subject.

Mr. Caldwell then communicated a series of notes detailing the process by which he had succeeded in producing through the interaction of triethylphosphine with monochloracetal and monochloraldehyde a new chemical compound—triethylphosphine chloraldehyde or "phosphorus muscarine." Triethylphosphine combines with monochloracetal to give $(OC_2H_5)_2$. CH. CH_2. P $(C_2H_5)_3$. Cl., triethylphosphine-monochloracetal, which, on treatment with concentrated hydrochloric acid, yields the aldehyde CHO. CH_2. P$(C_2H_5)_3$. Cl., triethylphosphine-chloraldehyde. Monobromacetal likewise combines with triethyl phosphine. Monochloraldehyde unites with triethyl phosphine, with the production of a syrup having a beautiful green fluorescence. The syrup placed *in vacuo* over sulphuric acid crystallises in a few days. Monobromaldehyde also combines with triethylphosphine, forming a crystalline compound. The structure of these compounds is CHO. CH_2. P $(C_2H_5)_3$ X., where X denotes chlorine or bromine. The salts of this compound have been prepared, and their properties are being studied. On account of the similarity of structure of this compound to the corresponding nitrogen compounds, and inasmuch as muscarine occupies an intermediate position to choline and betaine it is proposed at the present to name this compound phosphorus muscarine.

The **PRESIDENT** exhibited a series of sections and X-ray photographs of the upper end of the femur to illustrate the arrangement of the cancellous lamellæ and of the structure known as the calcar femorale. The calcar femorale was shown to represent the posterior aspect of the bent upper end of the tubular femur. The bent portion of the tubular bone becomes oval in transverse section. In the young bone, what is afterwards the calcar forms the posterior surface of the neck, but, with the development of the trochanters and the projections for muscular attachments this part of the surface is covered over and comes to lie deeply, remaining, however, visible in section. When carefully examined in sections the outer and upper part of the lamellæ forming the calcar are seen to bend forwards so as to become continuous with the lamellæ which mark off the great trochanter and which form the upper and outer part of the neck of the tubular bone. In the young bone, before the great trochanter has become united, these lamellæ also form a part of the surface. The spirally-arranged supporting lamellæ, formerly described by Dr. W. S. Haughton and the author, are attached in right and left-handed spirals to the deep aspect of these sunken parts of the surface of the neck of the bone, in precisely the same manner as to the other parts of the inner aspect of the hollow shaft and neck. The tubular nature of the neck and the disposition of the spirally-arranged supporting lamellæ are well seen in X-ray photographs. Further, the arrangements of the parts as seen in photographs and in sections can be reproduced in a model constructed with right and left-handed spirally-arranged thickenings, placed within a tube and bent in the same manner as the upper end of the femur. The calcar femorale and the lamellæ which mark off the great trochanter are parts of the surface in the young bone, and in the adult they form parts of the physiological surface of the bent portion of the femur, considered as a structure through which the weight of the body is transmitted. Hence the lamellæ of the cancellous tissue which fill the neck of the bone are attached to them in a manner similar to that in which lower down they are attached to the inner wall of the upper part of the shaft.

Prof. E. P. **M'LOUGHLIN** said that the communication threw quite a new light on the significance of the calcar, and the sections showed this structure to be very much more extensive than has been generally described.

TWO ADULT MALE SUBJECTS CUT IN THE LONG MEDIAN PLANE.

Prof. **FRASER** exhibited the above. One had been cut four or five weeks previously, and the other, an ordinary injected dissecting-room subject (not specially prepared), the day before the meeting. The latter formed an object-lesson in the description of the hollow abdominal viscera, having the largest stomach that he had ever seen. It was equably dilated from cardiac to pyloric orifice. It had distended the right and left aspects of the body wall, and appreciably diminished the size of both liver and spleen. He referred also to the varying relations of the ventral aorta to the sternum, to the presence of the embryonic cranial flexure in the adult, which did not cease with the bony dorsum sellæ, but extended as soft supporting tissue to the roof of the fossa inter-peduncularis, a point which had great significance in the numerous measurements of the skull. He also drew attention to the variations in the distance between the perineal skin covering and the posterior extension of the body cavity in both male and female, and more particularly in the young. These sections were very instructive, and much appreciated by students in the ordinary dissecting-room teaching.

BRITISH BANEOLOGICAL AND CLIMATOLOGICAL SOCIETY.

MEETING HELD WEDNESDAY, JANUARY 30TH.

The President, H. SHIRLEY JONES, Esq. (Droitwich) in the chair.

Dr. **C. W. BUCKLEY** (Buxton) introduced a discussion on the

INFLUENCE OF CLIMATE ON GOUT AND RHEUMATISM.

He said that gout was affected by climate so far as the functions of the liver and excretory system, comprising both kidneys and skin, were concerned. In patients who were fairly robust and without high arterial tension or arterio-sclerosis, a bracing climate was desirable; humidity should be low and temperature fairly equable. In cases with high tension a more relaxing climate is best, and inland climates are generally better than marine. The south-eastern counties show a remarkable excess of gout in comparison with other parts of the country, partly explained by the class of population, and perhaps partly by the chalky character of the water. Acute rheumatism was not affected by climate except so far as unfavourable climatic conditions might lower the resistance of the system to infection. Muscular rheumatism and kindred conditions which were best described as fibrositis were unfavourably influenced by a high humidity, and especially by a damp soil, but temperature was of less importance, equability being more essential than warmth. Free air access was important, and stuffy hollows to be avoided. For the foregoing diseases there did not appear to be any advantage in sending the patient abroad. In rheumatoid arthritis, however, the desirable combination of warmth, equability and low humidity was hardly attainable in this country, though low humidity was still the most important factor. Probably the best climates in this disease were those of the Grand Canary, Teneriffe and Bermuda.

Dr. **GROVES** (Isle of Wight) expressed general agreement with Dr. Buckley's views, and pointed out the unreliability of statistics in determining the effect of climate upon the diseases in question. For those of early middle and later life suffering from or having a tendency to rheumatic and gouty affections, an equable climate with a marine atmosphere, not too humid to admit of free diaphoresis in connection with exercise in a locality sheltered from cold winds, is the most suited.

Dr. **PERCY LEWIS** (Folkestone) held strongly the view that chalk in drinking water had nothing to do with the causation of gout. Gout and rheumatism were considerably more a matter of the habits of individuals than of the climate in which they happened to reside.

Dr. **BEGG** (Bath) considered the influence of climate comes down to a question of wear and tear, and its ability to lower the resisting power of the organism to disease, and in that way alone can it influence. He thought of climates as divided for clinical purposes into two classes: (1) the bracing, (2) the relaxing or sedative, and his principle of applying them to cases was that which governs his administration of stimulants. When he would use malt liquors and nourishing port, he advised a sedative climate, and when champagne and spirts, he recommended a bracing one; when he wanted to build up a reserve force, the sedative, and where he wished to influence metabolism, the bracing.

Dr. **LEONARD WILLIAMS** did not believe in the existence of a disease which could be properly called chronic rheumatism. Most of the cases so described were chronic gout or some septic form of arthritis. Goutily disposed people were better in bracing climates, those with definite gouty manifestations in kidneys or arteries ought never to be sent to bracing climates, but always to relaxing ones.

Dr. **TYSON** (Folkestone) said that until we knew more about the etiology of rheumatism we must adopt such clinical methods as have been found more or less useful, such as a dry climate, as much sun as possible, and attend to the general laws of health, as regards clothing, proper ventilation, and suitable foods.

Dr. **JOHN LEON** (Southsea) agreed that patients should be instructed how to adapt themselves better to the place in which they happened to live. He thought that gout (apart from renal changes) was little affected by climate. In Southsea, arthritic patients generally did well owing to the equable climate.

Dr. **F. THOMPSON** (Bath) said that during a residence in Oporto, among a community where port wine is freely indulged in, he was struck with the comparative rarity of gout, both acute and chronic. This he attributed largely to the effect of the warm climate causing constant free action of the skin. He considered warmth of locality to be an important factor in the climatic treatment of gout.

Dr. **BUCKLEY**, in reply, said he was in agreement with Dr. Groves as to the importance of humidity due to ground water, and was very glad to hear Dr. Tyson's interesting proof of this. He considered it was a matter worthy of more investigation. He still believed that chalky water had an influence in gout, and also that it is absorbed from the alimentary canal. As to sunshine, he also maintained that its influence in rheumatism is purely psychical, but in rheumatoid arthritis he thought it might be of more importance. He feared he did not make sufficiently clear that he drew a decided distinction between acute rheumatism and fibrositis, as he felt sure that he was really in agreement with some speakers who criticised him on this point, but on the subject of chronic rheumatism he was very glad to hear that Dr. Thompson agreed with him that there was most certainly an arthritic condition to which the term may be applied without confusing either rheumatoid arthritis, gonorrhœal, or any other form of rheumatism. The report on the prevalence of the diseases dealt with from the Lancashire coast bore out much that he said.

Dr. **GEO. THOMPSON** (Buxton) said that year after year he noticed that many gouty patients came to Buxton from the south-eastern counties and generally complained of the chalky water. He noticed that many cases of a chronic rheumatic arthritis at the Buxton Hospital came from certain humid districts—from valleys, from river districts, from the Fen district and from Ireland.

Dr. **HEANEY** (Blackpool) said Blackpool and district had a climate of high average humidity and a very low mean temperature: the country was flat and winds constantly prevailed. Chronic rheumatic arthritis occurred with great frequency. But acute rheumatism was almost unknown there owing to the fact that in a frequently renewed atmosphere acute rheumatism, like other infective diseases, is less likely to occur. Gout was very rare indeed on the West Coast of Lancashire.

WEST LONDON MEDICO-CHIRURGICAL SOCIETY.

Meeting held February 1st, 1907.

Mr. L. A. Bidwell, F.R.C.S., in the chair, in the absence of the President, Dr. L. A. Mark.

The following pathological specimens were shown.

The President: Drawings from specimens of cancer of the tongue.

Dr. Coutts: (*a*) Congenital malformation of the heart; (*b*) Purulent pericarditis; (*c*) tuberculous pneumothorax; (*d*) sarcoma of the bladder.

Mr. J. Pardoe: (*a*) Calculi in both kidneys and ureters; (*b*) malignant growth of bladder invading iliac vessels; (*c*) malignant hype nephroma.

Dr. Lionel Provis: (*a*) Fibroma of ovary; (*b*) adeno-myoma of uterus with microscopic sections.

Dr. Chisholm Williams: X-ray photographs and lantern slides of patients treated by X-rays.

Dr. David Arthur: Skiagraphs and orthodiagraphic tracings of cases of aneurysm and heart disease.

Mr. Cecil Leaf: (*a*) Cyst of the breast with intracystic growths; (*b*) multiple cystic tumour of the breast.

Mr. Aslett Baldwin: (*a*) Enlarged fasciculated bladder due to enlarged prostate; (*b*) appendix containing a mulberry calculus; (*c*) large gall-stone causing intestinal obstruction.

Dr. Macnaughton Jones: A collection of specimens of uncommon uterine and ovarian diseases.

Dr. E. F. Travers: An early vesicular mole.

Dr. J. M. Bernstein: (*a*) Phlegmonous gastritis; (*b*) Chorion epithelioma of the testis; (*c*) tissues invaded by Bilharzia. and other specimens.

Dr. Adamson: Cultures and micro-photographs of ringworm.

Dr. Norman Meachen: Microscopic specimens of Leucotrichia annularis (ringed hair).

Dr. Eddowes: (*a*) Microscopic specimens of gout of the skin; (*b*) microscopic specimens of diplococci of Denne and Dahnhardt.

Mr. Percy Dunn: (*a*) Glioma of the retina; (*b*) sarcoma of the upper lid; (*c*) staphyloma of the cornea.

Mr. E. D. Shaw: Carcinoma of testis with secondary deposits in glands and liver.

Dr. G. C. Low: (*a*) Plasmodium of malaria; (*b*) Filaria; (*c*) trypanomiasis, specimens of morbid anatomy.

Dr. J. H. Dauber: Specimens of uterine, ovarian and tubal disease.

ULSTER MEDICAL SOCIETY.

Meeting on February 7th, and adjourned Meeting on February 14th, 1907.

The President, Dr. D. P. Gaussen, in the Chair.

DISCUSSION ON CEREBRO-SPINAL MENINGITIS.

Professor Symmers opened the discussion by describing the *post-mortem* appearances in five cases which he had examined. In a typical case, which had died after two or three days' illness, the whole surface of the brain was found bathed in pus. The internal appearance of the brain was normal. In all cases there was a distinct pericarditis, and endocarditis in none. In two there was suppurative pericarditis. In the small intestine, and specially in its lower part, there was in every case undue hyperæmia, and distinct enteritis in two. The mesenteric glands were greatly enlarged, a point to which he called special attention. He found hyperæmia of the pelvis of the kidney, and signs of pyelitis in most cases, and extraordinary hyperæmia of the bladder in one. In one case an organism like the meningococcus was found in the mesenteric glands, suggesting the possibility that the child had died from disease spreading from the bowel. The meningococcus was almost identical both microscopically and on culture with two other organisms, the gonococcus and the micrococcus catarrhalis, the latter being found in the nose. Though generally considered as not staining by Gram's method, there was some reason to believe that it might so stain when the specimen was young and vigorous. It is exceedingly difficult to cultivate. It is found easily in the pus, but never in the blood. It is never found in animals, and as regards insects there is no positive evidence, though Dr. Turner, a South African writer, thinks he has found it in fleas. As regards the serum we lack knowledge as yet; it is difficult to see how it can be prepared from an organism so difficult to cultivate, or how it can be standardised when it is not infective for animals.

Dr. Robb (physician to the Fever Hospital), said it was too early to generalise, and all he could do was to describe the epidemic so far as he had seen it. They had had 37 cases admitted to hospital, of which 16 had died, and some more were very ill. In the first family affected, five members were admitted in four days, and of the next family five members were taken ill in less than twelve hours; four died in 30 hours, and the last ten days later. In two cases two members of a family were affected close together. In general characteristics the epidemic was more like one of acute pneumonia than anything else he had seen. One-third of the cases were of the acute fulminant type. König's sign was marked in practically all. There were no convulsions, and when death occurred it was from cardiac failure. In all the severe cases there was delirium, in some quite maniacal. The pupils were dilated in nearly all. The glands were enlarged and "shotty." Petechial spots were not common. Eye symptoms were not common; he had seen nystagmus twice and squint twice.

Professor Lindsay confined his remarks to a brief description of a case.

Dr. Calwell described two cases, leaving the most striking symptoms of one of them, the eye and ear symptoms, to be described by Dr. Cecil Shaw.

Dr. McCaw described five cases, most of them seen in the Belfast Children's Hospital. He also described several cases seen last autumn, which he now believed were cases of this disease. He did not believe in the contagiousness of the disease as generally accepted.

Dr. Cecil Shaw, who was absent owing to an attack of influenza, sent his notes to the hon. secretary, Dr. Howard Stevenson, who read them. They will be found in full on page 203.

Dr. Dempsey had seen four cases, and spoke specially of the differential diagnosis, which he thought was from acute pneumonia and typhoid.

Dr. Austin said he had seen the first case of the present epidemic, and had at first considered it one of ptomaine poisoning, as the patient had eaten largely of tinned salmon. There was a profuse purpuric eruption.

Dr. A. B. Mitchell spoke of the differential diagnosis from such affections as abscess of the brain. Drs. Darling, McKisack, Burns and O'Neill also spoke, and in the absence of Professor Symmers, Dr. Robb closed the discussion.

Vote of Condolence.—A vote of sympathy with the Rev. Dr. Graham, of Comber, co. Down, on the death of his son, Dr. R. A. L. Graham, was passed at the conclusion of the meeting.

CORRESPONDENCE

FROM OUR SPECIAL CORRESPONDENTS ABROAD.

FRANCE.

Paris, Feb. 17th, 1907.

Treatment of Sweating.

It is calculated that the average quantity of sweat evaporated from the body (in perceptible perspiration) in the normal state is about one pint. More marked in general on one side of the body, it shows itself with greater intensity in certain regions, such as the palms of the hands, etc. It is alkaline in its reaction, but can become acid by reason of fatty acids, and this acidity increases with organic combustions, but diminishes with the abundance of the secretion. Sweat is colourless, of a saline taste, and characteristic odour, which varies with individuals.

The secretion is stimulated under the influence of divers causes: elevation of the surrounding temperature, a considerable proportion of water in the blood, increase of cardiac activity and contraction of the blood-vessels, muscular exercise, effect of certain medicinal agents (pilocarpine, strychnine, camphor, preparations of ammonia). There exists a certain antagonism between perspiration and the urinary secretion.

Where the perspiration is excessive and persistent it becomes a morbid symptom, and belongs to the domain of therapeutics.

Sweating is either general (hyperhidrosis) or local (ephidrosis), and is either, says Professor Weber, idiopathic or symptomatic. As an isolated symptom it comprises all the varieties of partial sweats, and one very frequently occupying all the parts of the body—face, scalp, axillæ, groins, genital organs, palmar and plantar regions.

Facial ephidrosis accompanies sometimes migraine, facial neuralgia, or simple mastication. Perspiration of the head is observed in arthritic or gouty individuals, and can be one of the causes of early baldness. In the bend of certain joints the sweating provokes frequently irritation (intertigo) of the skin, as well as beneath the breasts in stout women. Excessive perspiration of the legs would be, according to Verneuil, a good sign in varicose veins.

In palmar ephidrosis the hands are cold and clammy, the patient is generally neurasthenic, but the same phenomena can be observed in incipient phthisis or in certain syphilitic women (secondary period).

Plantar ephidrosis is perhaps more frequent still, and almost always accompanied with a fetid odour, especially in red-haired individuals (bromidrosis).

In symptomatic sweating the sweat appears over the whole body. When very abundant it is accompanied by eruptions (erythema, sudaminæ) or intolerable itching.

In certain febrile affections, the perspiration is very abundant, and notably in that curious malady known as the sweating sickness, where the miliary eruption is general; its termination is announced by an abundant emission of urine.

Generally speaking, perspiration accompanies the defervescence of the febrile condition, but it can be provoked by the treatment employed (antipyrine, phenacetine, diaphoretic infusions).

On the other hand, it can constitute one of the symptoms of certain maladies, of which acute articular rheumatism holds the first place. Here hyperhidrosis is frequently very excessive, prolonging convalescence.

Sweating represents a crisis or turning point in many maladies, such as pneumonia, erysipelas, mumps, eruptive fevers, grippe, cerebro-spinal meningitis, chronic pulmonary tuberculosis.

Hyperhidrosis is observed in all cachectic conditions: uræmia, cancer, ataxy, infantile paralysis, and, above all, phthisis.

The treatment, says Professor Weber, of idiopathic sweating is very complex. As it generally belongs to persons of a nervous temperament, bromides, antispasmodics, hydrotherapy in all its forms should be employed.

Where the perspiration is observed in the course of a febrile affection, it should be respected in general, as it represents a providential emunctory, and in any case it is not very abundant, except in sweating sickness, when it plays a preponderating rôle.

Certain medicinal agents are specifics against sweating, quinine for that observed in ague, and salicylate of soda for that of acute rheumatism. But, on the other hand, the sweating resulting from cachexia is almost rebellious to all treatment. Tonic treatment of the system when possible is about the only remedy.

Generally speaking, as soon as the perspiration, by reason of its abundance, is capable of weakening the patient, the patient will be advised to change his linen, or even his clothes, to avoid refrigeration of the body from its rapid evaporation, and to rub his body immediately afterwards with a spirit lotion (lavender or eau-de-Cologne), and finally, if erythema be present, to powder with talc or starch.

As to drugs employed, their efficacy varies more or less. Those most prescribed are atropine ($^1/_{200}$), given every two hours in pills or tabloids up to five or six a day if necessary, agaric, camphoric acid. The atropine should be closely watched, as in some patients it produces toxic effects.

M. Weber recommends the following formulæ:—

Agaric, dr. 1.
Extract of opium, gr. 8.

Divide into 40 pills; 2 or 3 at night.

Or,

Tellurate of soda, gr. 2.
Proof spirit, oz. 2.

A teaspoonful morning and evening in sugared water.

This drug communicates an odour of garlic to the breath. It has been also accused of making the hair fall.

Or,

Camphoric acid, gr. 30.
Proof spirit. q.s.
Syrup of orange, dr. 4.
Water, oz. 2.

A teaspoonful to be taken two hours before the evening meal.

Or,

Ergotine, gr. 10.
Tannate of quinine, gr. 10

Divide into 20 pills; 2 or 3 in the evening.

Or,

Oxide of zinc, gr. 4.
Extract of belladona, gr. $^1/_5$

For one pill; 3 daily.

Perspiration of the hands and feet:

Hands:—

Borax, dr. 4.
Salicylic acid, dr. 4.
Boric acid, dr. 1.
Glycerine, oz. 2.
Proof spirit, oz. 2.
Water, oz. 2.

Rub the hands three times a day.

Feet:—

Fœtid sweating of the feet is very difficult to cure. General treatment is necessary (arthritism, lymphatism, anæmia, etc.). The patient should bathe the feet twice a day in an alum bath, to which is added half an ounce of borax and a tablespoonful of tincture of benzoin, besides which he will paint the toes with naphthol and glycerine (5 per cent.), and powder his stockings with—

Talc, oz. 2.
Subnitrate of bismuth, oz. 2.
Permanganate of potash, dr. 1.
Salicylate of soda, dr. ½.
Tannoform, dr. 2.

GERMANY.

Berlin, Feb. 17th, 1907.

AT the Verein für Innere Medizin, Hr. P. Fraenkel spoke on

POISONING BY LYSOL.

He said that very few opportunities occurred of obtaining preparations of poisonings by lysol, as when medical aid was at all timely, by far the greater number of cases recovered. He was in a position to show a stomach from a case of lysol poisoning. It was one in which nothing had been done for the patient, so that the changes produced by the poison were not influenced artificially. There was a great resemblance to poisoning by carbolic acid, only the soapy character of the mucous surface of the stomach and the alkaline reaction were the distinctions between the effects of the two poisons. Cauterisation of the stomach was frequently only superficial, but it was also often serious, and reached into the duodenum and jejunum. Sometimes no cauterisation at all was met with, notwithstanding a fatal termination, a proof that it played only a subordinate *role* in the poisoning.

Hr. Ewald spoke on

ULCERS OF THE STOMACH AND GENERAL CARCINOMA.

He said that the diagnosis of cancer of the stomach had now reached the "dead point"; the ordinary means of recognition were exhausted. With the large material that was at his hands, however, there were still cases that, from their atypical behaviour, were of interest, such as the following :—A woman, æt. 35, had typical hæmorrhage of the stomach at her nineteenth and thirty-second years. She had, however, completely recovered from her last attack, when in July last she began with pain and loss of appetite, with subsequent extreme loss of vigour and loss of weight, so that when admitted into the Augusta Hospital, the patient, who was a slightly-built woman, only weighed 27.4 kgm. Examination showed ptosis of the stomach, the lower border of which lay a hand's breadth below the umbilicus ; there was no palpable tumour, no glandular swelling. There was slight dulness over the base of both lungs posteriorly, vesicular breathing, slight rales, sputum was scarcely expectorated at all ; no tubercle bacilli were found in the small quantity that could be obtained. There was plenty of free hydrochloric acid in the stomach. A diagnosis of ulcer of the lesser curvature was made. During her stay in hospital, from December 24th to January 30th, 1907, the patient got steadily weaker, although her weight increased to 28.8 kgm. Towards the end of life the peculiar kind of breathing called by Kussmaul "grossesathem," or "big breathing," such as is observed in diabetic coma, came on. The patient died on January 30th. The autopsy showed deep falling of the transverse colonr, at the upper part of the stomach, which was placed vertically, was an hourglass contraction, and an ulcer on the lesser curvature. There were, moreover, cancerous metastases in all the abdominal organs ; the pancreas especially was full of them (no sugar had been found in the urine), and the lungs also. There were a number of cancerous nodules in the thoracic duct, probably a result of the transference of cancer material into the lungs. Possibly the case was one of primary cancer of the pancreas, and possibly also there was a slight cancerous degeneration of the gastric ulcer. During life there had been no symptoms of this, even if the rapid falling off of the patient's strength had pointed to it ; there was no lactic acid in the stomach, however, but on the contrary, copious free hydrochloric acid. The fever was not the hectic of cancer, but due to bacillary toxæmia.

At the Medical Society, Hr. G. Klemperer related a case of

SEPSIS FOLLOWING PYONEPHROSIS.

The patient had been brought into hospital ten days before under suspicion of typhoid fever. He was æt. 26, slightly feverish, heavy and dull ; he had free diarrhœa and meteorism. Besides this, there was dribbling of urine, which was mixed with pus. On the second day there was swelling of the right elbow-joint. A diagnosis was formed of sepsis following cystopyelitis. The patient's heart gradually failed, and he died. The autopsy revealed pronounced sacculated kidney (pyonephrosis) resulting from a large renal calculus. It was remarkable that but very slight symptoms had been set up by the calculus, and that then formidable symptoms of sepsis had suddenly developed. The calculus was formed of phosphates. This kind of calculus was not, therefore, so harmless as it was generally considered to be.

Hr. Westenhoeffer showed (and also at the Verein für Innere Medizin, on the 4th inst.) preparations from a case of

MENINGOCOCCOUS PHARYNGITIS.

A little girl, æt. 6, had died of typical epidemic cerebrospinal meningitis. At the autopsy the meningococcous pharyngitis described by the speaker was distinctly visible, and which was present in every case in the initial stages of the disease.

AUSTRIA.

Vienna, Feb. 17th. 1907.

PAPULOSIS PERSTASIS.

AT the Gesellschaft, Lang showed a young boy, æt. 15, with that disease which appears in literature under different names, such as pityriasis chronica lichenoides, &c., but which Lang considers more appropriately should be designated papulosis perstasis. The disease is somewhat mixed up with pityriasis and psoriasis, which it so resembles at different stages of its history that no clear conception can be formed from these compound terms.

The most interesting part in this case seems to be in the family history, where a sister of the patient had a similar cutaneous affection. The patient has suffered for the last seven years from an exanthematous eruption, varying from the size of a millet-seed to that of a pea, with a papulose appearance and depressed centre surrounded at the base with a reddish efflorescence from which a fine scurf could be rubbed off. This efflorescence was not well defined, but sometimes had a dark margin surrounding it. On the trunk these papules were strewn over in groups where they seem to be largest, leaving behind an atrophic cicatrix. The seventeen-year sister had cicatrices over the body varying in sizes similar to her brother, which were depressed in the normal skin but could be brought easily forward by a little traction ; but if the nail of the finger were again drawn over the part they sink back to their former position. These were white round markings well defined at the margin and having an umbilical appearance in the centre. According to her own history these recent changes occurred about two years ago, following an eruption similar to that of her brother five years previously. Her parents maintained that pustules never formed, and that all forms of treatment proved unavailing, as it has done in her brother just exhibited. It appears from these two histories that this is the turning point between the papular condition and the cicatricial state in which the sister is at present, and which Lang considers the term, papulose perstasis, to justify a full description of the case where it ends in atrophy.

Nobl remarked that the combination of psoriasis and lichenoid diseases were more easily defined than the above. He thought this disease lay more in the direction of a polymorphic eruption coming under the designation of "Pityriasis lichenoides chronica," which were annually becoming more frequent at our clinics.

ARTIFICIAL TEETH ACCIDENT.

Professor Chiari showed a young man, æt. 38, who accidentally swallowed his artificial teeth during sleep, thirty days before seeking any surgical advice. Several symptoms pointed to a foreign body in the œsophagus, but from the history of the case it was thought advisable to examine the canal with the Röntgen rays, when a shadow representing this body was observed behind the sternum, and in front of the spine. After cocainising the throat, an œsophagoscope was introduced ; when 20 cms. below the lower jaw a thick œdematous swelling was observed closing up the lumen, preventing the further passage of the instrument. Again painting the œdematous mucous membrane with cocaine, the instrument was further introduced and brought into contact with the foreign body. A smaller tube was then introduced, the foreign body caught, and the whole extracted without any force or injury to the parts. The teeth measured 4½ cms. in length, and 2½ cms in breadth. Freund related a similar case that he successfully operated on two years ago.

DR. HERBERT WILLIAMS, Medical Officer of Health for the Port of London, in his report, just issued, states that during the past two months twenty cases of beri-beri had been discovered on two vessels on their entering the river. There were 19 cases on the s.s. "Banca," of Sutherland, which came from Kobe and one on the ss. "Ava," of Glasgow, from Rangoon.

FROM OUR SPECIAL CORRESPONDENTS AT HOME.

SCOTLAND.

ROYAL COLLEGE OF PHYSICIANS' LABORATORY.—The council of the college have been fortunate in securing the services of Profesor Ritchie, Oxford, as superintendent of the Laboratory. The post has been vacant for more than six months, but this delay is more than compensated for by the announcement made last week. Professor Ritchie's return to Edinburgh will be welcomed by all his old friends, and it is felt that under his guidance the laboratory will again become a very important centre for scientific research.

CEREBRO-SPINAL MENINGITIS.—On February 12th the Local Government Board issued a circular requesting medical officers of health to report to them any cases of this disease which came under their notice, and offering advice and assistance where necessary. The board also advises that cerebro-spinal fever be made a notifiable disease for a limited period. According to corrected figures given by the superintendent of the Statistical Department, Register House, there have been, during January 1907, 66 deaths in Glasgow, 5 in Edinburgh, 1 in Paisley, and 2 in Leith. Since last May there have been 147 deaths in Glasgow from the disease. During the past week one or two more cases have occurred in Edinburgh, but the total number in this city is quite out of all proportion to the amount of attention which has been paid to the outbreak in the public press.

BELFAST.

CEREBRO-SPINAL MENINGITIS.—One or two new cases of this disease have been notified each day lately, but there has been no rapid spread of the epidemic. In all about 80 cases have been notified, with a mortality of 58 per cent. The affection has been made notifiable in all the districts round the city, and it is hardly likely that any cases can now escape the eye of the authorities.

TYPHOID AND THE WATER SUPPLY.—On the 13th inst., Professor Symmers wrote to the Public Health authorities saying that he had found in two samples of tap water which they had sent to him for examination an organism in every way identical with the bacillus of typhoid, so far as he had been able to carry his investigations. As a number of cases of typhoid have lately occurred in the district from which these samples of water were taken, the report has naturally caused considerable alarm. The Water Commissioners have telegraphed for their analyst and bacteriologist, Professor Frankland, to hold a consultation with Professor Symmers, and, meantime, the Public Health authorities have issued placards advising us to boil all water and milk before use.

DEATHS IN THE PROFESSION.—Two medical men have passed away during the past week, both sincerely mourned, but as wide as the poles asunder. One was the type of good old country practitioner, Dr. John Dysart, of Portglenone, Co. Antrim, who died in his 87th year, after sixty-four years in practice—a record not often surpassed. Dr. Robert A. L. Graham, on the other hand, was the best type of young specialist, a brilliant man, with a brilliant future, as all his friends thought. He graduated in Arts and Medicine at the Royal University, finishing in 1898, then studied in London, Freiburg, and Munich. He obtained the diploma in mental science in 1899, and the next year took the Hutchinson-Stewart Scholarship of £200. He was appointed assistant medical officer at the Belfast Asylum, and Demonstrator of Pathological Neurology in Queen's College. He brought a keen scientific mind and abundant enthusiasm to all his work, and it was always a pleasure to meet him in the College laboratories and talk with him over any medical problem. He was singularly modest and retiring, and it is not too much to say that he was more than liked, he was loved by all with whom he had to do. Three weeks ago he contracted typhoid, from which he died on February 13.

LETTERS TO THE EDITOR.

AN ANTI-VACCINATION ORATION.

To the Editor of the MEDICAL PRESS AND CIRCULAR.

SIR,—It must have been a proud moment for Mr. Lupton when he arose on Thursday evening last in the House of Commons to move an amendment to the Address demanding the repeal of the penal clauses of the Vaccination Acts. The Editors of *The Times*, who always give the fullest reports of distinguished speakers, were no doubt filled with dismay when they found that owing to pressure upon their space they could not afford room for more than a meagre summary of what was evidently a deeply reasoned, as well as an eloquent discourse. The curious thing is that not only the statements as to facts, but also the frequent impassioned outbursts were punctuated throughout with "laughter." To us it seems that the speech might almost have made the angels weep. What could be more blood-curdling than the hon. member's denunciation of "the most wicked invention, that of opening a vein, cutting through the skin and putting into it pus from a diseased cow"? Then fancy the levity of hon. members laughing continuously at passages like these:—"The human race had existed for a long time, and they were all proud of its history. They had read of Moses and David, of great conquerors like Alexander and Cæsar, Demosthenes and Cicero, Nelson, Wellington, and Napoleon; and this country claimed the parentage of such men as Spenser, Shakespeare, and Milton. Did any hon. member believe that these men had been vaccinated?" This oration was not needed to enable the world to form a correct estimate of the intellectual calibre of the chief champion of anti-vaccination—he had furnished more than enough evidence already. What, one asks, can be the mental capacity of followers led by chiefs of this quality, and how much consideration do their childish outcries deserve from the Government of a people claiming a front rank in civilisation and enlightenment? I am, Sir, yours truly,

Bradford. ONLOOKER.

THE UNIVERSITY QUESTION.

To the Editor of THE MEDICAL PRESS AND CIRCULAR.

SIR,—The Dublin University Defence Committee have issued the appended Form of Protest for signature by all Graduates of the University. Will you kindly allow us to give it publicity through your columns, and to request Graduates either (*a*) to call at No. 35, Trinity College, Dublin, and affix their signatures; or (*b*) to authorise us by letter to do so on their behalf?

We are, Sir, yours truly,
EDWARD P. CULVERWELL,
EDWARD GWYNN, Hon. Secs.
Dublin University Defence Committee,
35, Trinity College, Dublin.
February 12th, 1907.

FORM OF PROTEST.

I desire to record my protest against the reconstruction of the University of Dublin outlined in Mr. Bryce's speech of January 25th, 1907, which I regard as fatal to the best interests of liberal University education in Ireland, and unjust to Trinity College.

THE FALLING BIRTH-RATE.

To the Editor of THE MEDICAL PRESS AND CIRCULAR.

SIR,—The falling birth-rate has, within late years, formed the subject of a most exhaustive discussion from almost every conceivable point of view in your pages, and I do not propose to re-open it now. It may be well, however, to note a few salient facts from the Registrar-General's Report for 1905, just issued. The total births for the year constitute the lowest rate since civil registration was established, and mark the steady progress of a fall which has continued since 1876. The significant fact is pointed out that up to 1882 there were six European States in which the fertility of wives was less than that in England, whilst now the rate in England is lower than that of any European country excepting France. It is noted, further, that the rate of fertility amongst wives has fallen below the level prevailing in New South Wales. About 17 per cent. of the total decline in the birth-rate is due to a decrease in the proportion of married women of conceptive ages, and 10 per cent. is due to decrease of illegitimacy. The most suggestive statement derivable from the report is that which points out that the greater part of the remaining 73 per cent. of the fall is due to the deliberate restriction of child-bearing on the part of parents themselves.

In the hope that some of your readers may contribute to the discussion of this vitally important subject, I remain, yours truly,

London, February 18th, 1907. M.O.H.

THE VAGRANT ACT.

To the Editor of THE MEDICAL PRESS AND CIRCULAR.

SIR,—According to reports in the daily papers, several of the recent sentences at the County of London Sessions were for so-called indecency, but as the birch rod was ordered as well as a term of imprisonment, the men must have been convicted under the Vagrant Act, of which indecency is one of a number of offences for which the punishment of the birch rod is admissible.

It is admitted on all hands that the power possessed by magistrates presiding at Quarter Sessions in regard to the infliction of corporal punishment under an ancient Act of Parliament should be taken away in the interests of the community. One can hardly believe that in Christian England—the country of the free—men are birched for begging and sleeping out. Yet a recent return issued by the Home Office shows that out of 11 such birchings inflicted during 1905 and 1906 5 were passed by the Dorset Shallows for sleeping out!

Ten years ago Sir Mathew White Ridley (who was strongly opposed to flogging for many offences) brought in an amendment of the Vagrant Act which provided for the abolition of birching by leaving out Section 10, under which such punishment is authorised. But the Lords restored the power, and the Home Office of that day was too feeble to resist. Later a Bill was introduced into the House of Commons which proposed to abolish flogging for vagrancy. The proposal received the support of the Association of Chairmen of Quarter Sessions, but as the Bill had for its main object the extension of flogging in other directions, it was defeated by an overwhelming majority.

I believe that if a short Bill were brought forward to abolish flogging for vagrancy, the present democratic House of Commons would pass it without a division. Yours truly,

February, 1907. AMATEUR CASUAL.

OBITUARY.

JAMES EDMUND HUXLEY, M.D., M.R.C.S., L.S.A.

WE are sorry to announce the death of Dr. James Huxley, which took place at Maidstone last week. Dr. Huxley was brother of the late Professor Huxley, and though he did not attain the pre-eminent scientific position of his distinguished relative, he held for many years the post of Medical Superintendent of the Barming Heath Asylum, where his skill and administrative abilities had full play. Dr. Huxley, who was 87 years of age, took the M.R.C.S. of England as long ago as 1843, followed by the M.D. of St. Andrews and the L.S.A. in the following year.

ROBERT THOMSON FORBES, M.B., C.M., GLASG.

WE regret to chronicle the death, at Sandiacre, near Nottingham, of Dr. Robert Thomson Forbes, formerly a medical practitioner in Moffat. Deceased, who was 57 years of age, was a son of the late Rev. John Forbes, parish minister at Symington. He was one of the promoters of the original company which started the Moffat Hydropathic, which was opened in 1878, and for a number of years acted as a director and resident physician of the establishment. He was educated at Glasgow University, and took the degrees of M.B. and C.M. in 1871.

SPECIAL ARTICLE

UNIVERSITY EDUCATION IN IRELAND.

THE most important occurrences during the past week in what may be described as the University battle have been, first, the sending of a deputation by Trinity College to Mr. Birrell and to Mr. Balfour, and, secondly, the announcement by Mr. Birrell that a University Bill would be introduced at an early date. The deputation from Trinity College consisted of Dr. Anthony Trail, the Provost; Rev. T. T. Gray, Senior Fellow; Mr. Beare, Professor of Greek; Mr. Edward Gwynne, representing the Junior Fellows; and Sir Charles Ball and Professor Joly representing the Professors. The proceedings were private, and all that is known of them is that it is believed the interview with Mr. Balfour was of a more satisfactory character from the Dublin University point of view than that with Mr. Birrell. Indeed, it is evident from subsequent proceedings in Parliament that both Mr. Balfour and Lord Lansdowne intend to oppose any attempts to interfere with the University of Dublin.

Sir West Ridgeway, in a letter to *The Times*, strongly condemns Mr. Bryce's scheme as following the line of most resistance and as retrograde. He also points out that Trinity College has many friends on both sides of the house who will fight desperately in defence of its interests. He outlines an alternative scheme as follows:—"The two thriving colleges in Ireland outside Trinity College are the Protestant Queen's College at Belfast and the Roman Catholic University College at Dublin. Both, especially the latter, require more money for their development. Increase the funds at the disposal of the Royal University, and leave the Senate to make the necessary grants to both institutions, sufficient to provide University College, like Queen's College, Belfast, with the necessary buildings which it now so sadly requires. The condition might be imposed that there are to be no tests, that the Colleges should be open to students of all creeds, and that the majority of the governing body should be laymen. I believe that this compromise would be accepted by the Irish Roman Catholic Hierarchy, that it would not be too bitterly opposed by the Orangemen of Ulster, and I do not understand how English Nonconformists could reasonably object. It is not an ideal settlement; it is not final, but it is practicable, and it is capable of automatic development. There will be no destruction. Trinity College will not be touched, the Royal University will be preserved, and even Queen's College, Galway, will be given breathing time. Above all, there need be no legislation."

A meeting of the Higher Education Committee of the Presbyterian Church has been held, but as yet no pronouncement of its views has been made. A subcommittee has, however, been appointed to prepare a report on the subject, and to submit it to a further meeting of the Committee.

As will be seen from a letter which appears elsewhere in the present issue, a "Form of Protest" has been drawn up by Trinity College, and all Graduates of the University have been asked to sign it. Another protest in the following terms has been drawn up by the Alumni Association, Queen's College, Galway:—"We, the undersigned members of the Alumni Association of Queen's College, Galway, protest against the attempt to place our Alma Mater in a position inferior to that of the other Queen's Colleges in the new University scheme proposed by the Government."

On the other hand, a declaration in favour of Mr. Bryce's scheme has been drawn up by the Catholic Graduates and Undergraduates' Association and is being circulated for general signature. It states that the scheme "merits our strongest support; and we affirm our conviction that to be in consonance with Catholic ideas and acceptable to the Irish people, such new College must (1) possess whatever faculties in Arts and Science, equipment, academic privilege, and public endowment any other constituent college of the common University may possess, and should (2) be granted the fullest possible measure of autonomy."

WEEKLY SUMMARY OF MEDICAL LITERATURE, ENGLISH AND FOREIGN.

Specially compiled for THE MEDICAL PRESS AND CIRCULAR.

RECENT PATHOLOGICAL LITERATURE.

Salomon's Test for Gastric Carcinoma.—After a period of twenty-four hours on fluid and albumin-free diet, Salomon washes out the stomach in the evening, and again on the following morning with physiological saline solution. He states that the morning fluid gives an intense cloudy precipitate with Esbach's re-agent in all cases of gastric cancer, while no such deposit is obtained in chronic gastric catarrh, in gastroptosis, or in nervous dyspepsia. According to Reicher *(Archiv. für Verdauung's Krankheiten*, Bd. xii., Hft. iii.), this test depends upon the exclusion of mucin and its peptone-like reduction products. Albumoses and peptones are always present in small quantities, but they cannot influence the test. Nucleo-proteids and purin bases derived from the nuclei of degenerating cells give a very delicate cloudiness in normal cases; but cloudiness followed by a flocculent deposit is strong evidence in favour of the presence of an ulcerated carcinoma. In order that the test may be of any value the washing must not be mixed with food products. M.

The Various Types of Carcinoma Cervicis Uteri.—The *Johns Hopkins Hospital Bulletin* for January, 1907, contains an important paper on the above subject by Professor Sampson. It embodies the result of 27 examinations made on specimens removed by abdominal operation, and on one specimen obtained at autopsy. The author divides the varieties according to their histological structure, their topography, and their morphology as follows:—(*a*) Squamous-celled and columnar-celled; (*b*) those of the vaginal portion of the cervix, and those within the cervical canal; (*c*) everting, cauliflower type, and inverting ulcerative type. He discusses the types *seriatim*. i. Squamous-celled carcinoma of the portio vaginalis—everting. This may occur as a pedunculated or sessile tumour, often of large size. Clinically, it bleeds readily, and is the least malignant of cervical cancers. ii. Squamous-celled cancer of the portio vaginalis—inverting. This is the most common form of cervical cancer; it is of the scirrhus type, and spreads deeply, often involving the parametrium early in the disease, and reaching the bladder. Clinically, it is very malignant. The inverting and everting types are not sharply defined from one another, but may co-exist. iii. Squamous-celled cancer of cervical canal—everting. This is a rare type, and presents the important clinical feature of indentation, retraction, and puckering of the portio vaginalis caused by the growth invading it from above. iv. Squamous-celled cancer of cervical canal—inverting. In this type bleeding is often a late symptom. The cancer tends to spread chiefly in the cervix itself, so that the cervix may be converted into a thin shell lined by cancerous tissues. Ultimately, however, it extends to the surrounding parts. v. Adeno-carcinoma of the cervix. This is apparently the most malignant of all the cancers of the cervix. It is usually of the everting type, and may give rise to extensive metastases. Recurrence seems liable to take place even after very early removal. M.

The Blood of Normal Young Adults.—Dr. Emerson puts on record the results of blood examinations made during the last few years on the students at the Johns Hopkins University (*Johns Hopkins Hospital Bulletin*, January, 1907). The red cells have been enumerated on several occasions in 171 different individuals, aged from 23 to 35 years, and the extreme limits in number per cm. were found to be 4,500,000 and 6,800,000. The average number appears to be about five and a half million, and this does not vary with age, as is shown by separate tabulation of the students between 23 and 28 years of age, as compared with the entire number of students. As most of the counts have been made in the autumn and winter, the records cannot show any seasonal variation; but as far as they go they seem to point to some changes occurring at the different periods of the year. In estimating the hæmoglobin, it has been found necessary to revert to the use of one instrument, in order to obtain satisfactory results, and the one now being employed is the new Sahli hæmometer. The results obtained with the use of other instruments gave a colour index of about .87, while 21 examinations gave an average ot 2.63 grams total hæmoglobin per 1,000,000 red cells. The white cell counts gave an average in 167 cases of 8,400 cells per cm., but the variations were from two to fourteen thousand. The averages obtained in women students, 16 in number, were slightly below the above figures both for red and white cells and for hæmoglobin. M.

Cammidge's "Pancreatic Reaction" in the Urine.—Dr. Cammidge defends this test, as now employed, in the *Edinburgh Medical Journal* for February, 1907. The present technic is as follows: 40 cc. of filtered urine, from a twenty-four hours' sample, free from albumin, sugar, and bile is taken, and to it is added 2 cc. of strong hydrochloric acid. The mixture is gently boiled on a sand bath for ten minutes, and, after cooling, is again made up to 40 cc. by the addition of water. The acid is then neutralised by the addition of 8 grammes of lead carbonate, and the mixture filtered. Eight grammes of tribasic lead acetate are now added to the filtrate, and filtration is again performed, after which the excess of lead is removed by sulphuretted hydrogen, and the solution filtered. Ten cc. are now taken, and made up to 17 cc. by adding distilled water; then 2 grammes of sodium acetate and .8 gr. of phenyl hydrazine hydrochlorate are poured in, along with a little dilute acetic acid. The mixture is boiled for ten minutes and set aside to cool, when in positive cases a yellow flocculent precipitate slowly forms. Dr. Cammidge has examined 400 urines by this test in the last two years, and claims a large amount of success in diagnosis by relying upon it. M.

The Diagnosis of Gastric Ulceration.—Hemmeter describes a new test for the diagnosis of gastric ulcer (*Archiv. für Verdauung's Krank.*, Bd. xii., Hft. 5). The patient takes at night time a large glass of warm water with a drachm of bismuth subnitrate. If no food is taken the bismuth should have disappeared from the gastric mucous membrane in from three to six hours; but if any ulcerated patches exist the bismuth will adhere for from 24 to 36 hours, and this persistence can be detected by means of X-rays. In order to make the test of value in the detection of the site of the ulcer, photographs must be taken from different positions, and, as a rule, mere screening is not sufficent to complete the diagnosis. M.

A Hitherto Undescribed Urinary Sediment.—Richartz (*Zentralblatt für Innere Medizin)* describes the case of a patient, æt. 44, of a neurotic disposition, who came to him complaining that his urine was cloudy and white. On first examination by ordinary tests the condition was regarded as being ordinary phosphaturia, but when the sediment was examined under the microscope, it was found to consist of very large crystals, some of which were 1.5 mm. in length, and from .3 to .6 mm. wide. In appearance they somewhat resembled sheaves of corn, similar to tyrosin crystals, but on a larger scale. Each needle of the sheaf ended in a sharp point, and the entire crystal was quite colourless. The writer, after examining them thoroughly, comes to the conclusion that they may be calcium diphosphate crystals, as they possess many points in common with the known crystals of that salt, but calcium diphosphate in the sense only that one atom of calcium had been displaced by magnesium and ammonium, so as to produce the formula Mg. Ca. $(NH_4)_2$ $(PO_4)_2$. The crystals were only occasionally present, and appeared to be only found when the patient was on a vegetable diet. M.

Functions of the Nucleus.—Adami (*Brit. Med. Journ.* December 22nd, 1906) discusses the physiology and pathology of the nucleus. His main thesis is that the nuclear matter controls all the essential activities of the cell. (1) A cell which has lost its nucleus, either naturally or artificially, may continue to live for a considerable time, but neither grows nor reproduces itself. Such a cell may exhibit some metabolic activities, but the higher metabolic activities are absent. (2) The nucleus undergoes certain gross changes during the activity of the cell. Thus, in some cases, it alters its position; in others it alters its shape. (3) Certain minute changes in the cell during activity start from the nucleus. Thus, Ogata showed that in secreting cells there is a passage of small granules from the nucleus into the protoplasm. His observations have been supported by Lukjanow, Macallum, Carlier, and several others. Macallum has shown a similar process in the developing ova of the Lake lizard and of the frog, and Thies in the nectar cells of flowers. (3) In various pathological processes, changes in the nucleus are concurrent with changes in the cell. Thus, it is generally admitted that in tumour formation there is an excessive but disorderly activity of the nucleus, shown by atypical and irregular mitoses. In the various degenerative processes, the nucleus, equally with the cell-protoplasm, undergoes morbid changes. (5) Viewed from the chemical side, the nuclear material is found to possess potentialities superior to those of any ordinary constituent of the cell body. (6) The nucleus is, as Loeb has shown, the centre of the oxidative processes of the cell, and it is also, in all probability, the most essential part in the production of ferments. R.

Carbon Monoxide Poisoning.—Nasmith and Graham (*Journal of Physiology*, December 29th, 1906) publish the account of an investigation into the action of carbon monoxide on the body, and particularly on the blood. The animal employed was the guinea-pig, and the usual method was to expose the pig continuously to such an atmosphere of mixed air and coal-gas as would saturate a definite proportion of the animal's hæmoglobin with carbon monoxide. The authors conclude:—(1) Carbon monoxide acts as a poison solely by its ability to prevent the normal supply of oxygen from reaching the tissues, and thereby deranging normal metabolism. (2) Guinea-pigs living continuously in a dilute carbon monoxide atmosphere so that the oxygen-carrying power of the blood is diminished, are able, by increasing the quantity of hæmoglobin and the number of red corpuscles, to compensate for this loss and maintain an oxygen-carrying capacity approximately normal. The experiments supporting this statement were made by exposing animals to such an atmosphere as caused 25 per cent. saturation of the hæmoglobin with carbon monoxide. As a rule, on the second day the blood showed degeneration of the erythrocytes, and on the third normoblasts appeared. After a few days the degeneration disappeared, and the number of corpuscles rose to the normal, keeping thereafter at a fairly steady level. The animal kept in good health, usually becoming fatter. In a similar manner the amount of hæmoglobin gradually increased to reach a little above the normal. In animals exposed to atmospheres causing higher saturations, the damage to the red corpuscles was extreme, the protoplasm being almost completely destroyed. Nevertheless, it was found that some animals developed a compensation to 35 per cent. saturation, but 50 per cent. saturation, if prolonged, was fatal. (3) Carbon monoxide poisoning gives rise to a leucocytosis of the eosinophil and pseudo-eosinophil forms. A moderate saturation produced a moderate toxæmia involving, like other moderate toxæmias, an eosinophilia. A high saturation caused a severe toxæmia, in which, as in other toxæmias, the eosinophilia disappeared. (4) The effects of carbon monoxide on the number of the red blood corpuscles are similar to those of high altitudes. If the conclusions may be safely translated from animals to man, then it will follow that chronic carbon monoxide poisoning does not occur, nor is it a cause of anæmia. R.

Experimental Lymphocytosis.—Harvey (*Journal of Physiology*, December 29th, 1906) investigates the mode by which pilocarpin and other drugs cause lymphocytosis. It had often been noticed that the exhibition of pilocarpin caused an immediate crowding of the vessels with lymphocytes. In an ordinary leucocytosis, on the other hand, the increase in the number of cells is gradual, taking at least a couple of hours to reach its maximum. As pilocarpin causes active contraction of the muscle of the spleen and lymphatic glands, it was thought that this might be the explanation of the lymphocytosis. It was found that when the splenic vessels of a cat were cut, pilocarpin had no effect in the direction of lymphocytosis. On the other hand, stimulation of the splenic nerve in a dog caused a lymphocytosis similar to that induced by drugs. Atropin, moreover, inhibits the effect, if it precede the administration of the other drug. Harvey concludes, therefore, that the lymphocytosis caused by pilocarpin, muscarin, or barium chloride is a purely mechanical one, brought about by the contraction of the plain muscle of the spleen and lymph glands. R.

Diurnal Variations in the Excretion of Uric Acid.—Leathes (*Journal of Physiology*, December 29th, 1906) describes certain diurnal variations to which the excretion of uric acid is subject. He finds that when a uniform purin-free diet is taken, the excretion of uric acid is most active in the early waking hours and much less active at night. This cannot be due to a change in renal activity, since the excretion of nitrogenous substances in general is as high by night as by day. It must, therefore, be due to a variation in the formation of uric acid. Leathes also observed similar but less marked variations in the excretion of creatinin. R.

Human Chyle.—Hamill (*Journal of Physiology*, December 29th, 1906) has had an unusual opportunity of examining human chyle in the case of a patient suffering from chylous fistula in the right groin. (1) Human chyle varies in colour from bluish-white to yellowish as its fat-content increases. Its reaction is alkaline, and it clots rapidly on removal from the body. Oxalates prevent its clotting. Microscopically, fine particles of fat, leucocytes, and a few red corpuscles are found. As much as five litres of chyle was collected in twelve hours. The experiment had than to be stopped, owing to the exhaustion produced. (2) The fat content varied considerably during the day, being greatest six hours after the principal meal. (3) When a mixture of higher and lower fats is given in the food, the ratio of the higher to the lower fats is greater in the chyle than in the food. (4) Petroleum given by the mouth cannot be recovered from the chyle. R.

Paratyphoid Fever.—Since the first recognition of paratyphoid fever some five or six years ago, the number of cases on record has rapidly increased, and the disease cannot now be regarded as a rare one. Castellani (*Lancet*, February 2nd, 1907) describes thirteen cases of one or other type of the disease which have come under his notice in a comparatively short space of time in Ceylon. In six of the cases an organism identical with the "Paratyphoid A (Brian and Kayser)" was isolated. One of these cases ended fatally, the ileum presenting ulcerations identical with those of typhoid fever; the typhoid bacillus, however, was absent, but the paratyphoid A was recovered in pure culture from the spleen and lymphatic glands, and was found with the bacillus coli and other organisms in the ulcers. In one case there was a concurrent staphylococcæmia, which gave rise to boils. In the remaining seven cases the "Paratyphoid B (Shotmüller) bacillus" was found. In one there was a concurrent malaria, in one a concurrent pneumococcæmia, and in one a concurrent typhoid infection. The last case gave serum reactions to both organisms, and both were recovered from the stools. R.

MEDICAL NEWS IN BRIEF.

Royal College of Surgeons, England.

HUNTERIAN FESTIVAL.

The 179th anniversary of the birth of John Hunter, the founder of the museum of the College, was celebrated at the Royal College of Surgeons on Thursday last. In the afternoon, Mr. Henry T. Butlin, D.C.L., Consulting Surgeon to St. Bartholomew's Hospital, delivered an oration before a large company, and in the evening about 100 guests dined at the College at the invitation of the President and Council.

Mr. Butlin's oration dealt mainly with the objects of the life of John Hunter, and the manner in which he accomplished them. After describing the condition of surgery at the time of Hunter's birth as "composed of a vast unwieldy mass of observation and experience balanced on a single point, the study of anatomy," the orator narrated how, in the year 1748, a young man arrived in London from the North, who had spent most of his time in country sports, and it is probable that no person at that time would have ventured to predict that this same young man—"Jack Hunter"—would not only display a life-long industry, but would leave behind him a reputation which, as the College celebrations of yesterday proved, "is born of our conviction of his value to the art of surgery, and, as a natural corollary, the human race."

The history of Hunter's life affords an excellent example of the moulding of a man's character. Anatomy itself attracted him, and he threw himself into the study of it with much success. Many a young man, said the lecturer, may have gone thus far and their remained, content with the occupation for a livelihood and for the pleasure it gave him. Happily, Hunter's ambition urged him to become a surgeon, and he began to attend the Chelsea Hospital, and, subsequently, at St. Bartholomew's and St. George's Hospitals. Failing health, however, forced him to leave London, and he became a military surgeon. His duties in this latter capacity impressed him with an interest in the maladies in human beings which never left him, and which directed his scientific investigations to the elucidation of the problems of health and disease.

About the period of middle life he returned to London and began to build up what was destined to be a unique collection of specimens, dissected and prepared by himself. This formed the nucleus of the collection which was purchased, after Hunter's death, by Parliament for a sum of £15,000. The collection was offered to the College predecessors, the Corporation of Surgeons, and was accepted by them. And, said the lecturer, in conclusion, "to the glory of the college be it said, that one of the chief objects of generation after generation of our Councils has been, not merely to maintain the Hunterian Museum, but to enlarge and perfect it, until at this moment the Council of the College can exhibit it as the best museum of its kind in the world."

HUNTERIAN DINNER.

Among the guests entertained by the President (Mr. Henry Morris) and Vice-Presidents (Mr. Edmund Owen and Mr. Rickman J. Godlee) were: Prince Francis of Teck, the Earl of Onslow, Lord Reay, Lord Cheylesmore, Sir Schomberg McDonnell, Sir Herbert Maxwell, the deputy master of the Mint, Sir Edward Carson, Mr. Justice Bargrave Deane, the President of the Royal College of Physicians, the Vice-Chancellor of Cambridge University, the principal of London University, Archdeacon Sinclair, the President of the Institution of Civil Engineers, Sir William Church, Sir James Reid, Vice-Admiral Neville-Rolfe, Sir William Collins, Mr. Alderman and Sheriff Crosby, Mr. Sheriff Dunn, the Director-General of the Medical Department of the Royal Navy, the Director-General of the Army Medical Service, Sir John Wolfe Barry, Sir Charles Stanford, the Provost of University College, the treasurer of the Inner Temple, the treasurer of Gray's Inn, Sir Squire Bancroft, Sir Frederick Bridge, Mr. J. W. Waterhouse, the Masters of the Mercers, Grocers, Drapers, Clothworkers, Apothecaries and Barbers Companies, Sir Douglas Straight, Sir John Macfadyean, Sir Edward Henry, Sir Thomas Smith, Mr. Jonathan Hutchinson, Mr. Thomas Bryant, Dr. J. Kingston Fowler, Professor Clifford Allbutt, Mr. Ernest Page, Dr. Dawson Williams, and Mr. T. H. Wakley, together with sixteen members of the Council and the following officials: Professor Stewart, Conservator; Mr. Plarr, Librarian; and Mr. Cowell, Secretary.

After the usual Royal Toasts had been duly honoured, the Vice-President, Mr. Edmund Owen, proposed the Visitors, which was responded to by the Earl of Onslow, Sir Herbert Maxwell, and Mr. Justice Bargrave Deane. Sir Martin Rucker proposed the toast of the Hunterian Orator, which was responded to by Mr. Henry T. Butlin.

Vaccination Exemptions.—Important Government Action.

ON behalf of the Government the following statement was made in the House of Commons on the 15th instant:—

Dr. Macnamara (Camberwell, N.) said he rose to speak on behalf of the Government for the first time upon one of the most controversial questions in the whole range of public affairs. The expert anti-vaccinator had got up and bombarded the House with absolutely irrefutable figures, proving that vaccination was a barbarous and silly operation, fraught with real danger to the health of the person undergoing it. Directly he sat down up got the expert pro-vaccinator, and quoted equally reliable figures, showing vaccination was a vital necessity to the health of the community. No statistics were, in his opinion, more perplexing, unless they were tariff reform statistics. In his infancy his parents in their wisdom had him vaccinated. But neither side were entitled to claim him on account of that, because he was not consulted in the matter beforehand. In consequence of that operation, according to the view of the hon. member for Sleaford, he ought now to have died a hundred horrible deaths. On the other hand, he was comforted by the hon. and learned member for Kingston, who really convinced him that it was due to the fact of his having been been vaccinated that he was alive now to tell the tale. Be that as it may, the solid fact remained that from 1853 onwards there had been an increasing agitation against compulsory vaccination. His own view of that was that what ultimately became an objection to the operation itself originated in an objection to the manner in which it was carried out. As a result of the prolonged labours of the Vaccination Commission, the Act of 1898 once and for all gave up compulsion. But it could not be denied that a great many of our magistrates, challenging the wisdom of this Act, deliberately set themselves to make the obtaining of a certificate of exemption as onerous as possible. They frequently went out of their way to pour ridicule and contumely upon people who were availing themselves of the benefit of the law, and they inconvenienced them in every possible way. In some cases magistrates made a most contemptible discrimination between a rich man on the one side and a poor man applying for this relief on the other. This was not consonant with the spirit, to say nothing of the letter, of the Act. On behalf of the President of the Local Government Board, he had to say that it was proposed to substitute for the present system, under which a parent must obtain a certificate of conscientious objection, a new system, which would enable a conscientious objector to secure exemption upon making an ordinary statutory declaration. The Government desired to make general what was obviously a practice with the Kingston Bench. The President of the Local Government Board was not in a position to indicate more definitely the nature of his proposal, but it was intended to make the new procedure as little onerous as possible.

NOTICES TO CORRESPONDENTS, &c.

☛ **CORRESPONDENTS** requiring a reply in this column are particularly requested to make use of a *Distinctive Signature or Initial*, and to avoid the practice of signing themselves "Reader," "Subscriber," "Old Subscriber," &c. Much confusion will be spared by attention to this rule.

ORIGINAL ARTICLES OR LETTERS intended for publication should be written on one side of the paper only, and must be authenticated with the name and address of the writer, not necessarily for publication but as evidence of identity.

SUBSCRIPTIONS.

SUBSCRIPTIONS may commence at any date, but the two volumes each year begin on January 1st and July 1st respectively. Terms per annum, 21s.; post free at home or abroad. Foreign subscriptions must be paid in advance. For India Messrs. Thacker, Spink and Co., of Calcutta, are our officially-appointed agents. Indian subscriptions are Rs. 15.12.

ADVERTISEMENTS.

FOR ONE INSERTION:—Whole Page, £5; Half Page, £2 10s.; Quarter Page, £1 5s.; One-eighth, 12s. 6d.

The following reductions are made for a series:—Whole Page, 13 insertions, at £3 10s.; 26 at £3 3s.; 52 insertions at £3, and pro rata for smaller spaces,

Small announcements of Practices, Assistancies, Vacancies, Books, &c.—Seven lines or under (70 words), 4s. 6d. per insertion; 6d. per line beyond.

HAIR-GROWING BY MACHINERY.

DEAR SIR,—We should be obliged if you will inform us your lowest charges for the insertion, next to reading matter, of the enclosed advertisement in your publications once a week for a period of one year, we to provide you with a block. A NOTICE TO BE WRITTEN BY YOU ON THE ADVANTAGES OF THE CAP TO APPEAR ONCE EVERY THREE MONTHS; we to be at liberty to vary the advertisement once every three months. A copy of your publications with advertisement to be sent to us each week.

Yours faithfully,
The Evans Vacuum Cap Co., Ltd.,
J. R. HANBURY, Manager.

P.S.—We will furnish you with the material necessary for the notice above referred to.

[The foregoing letter refers to a kind of vacuum apparatus to be affixed to the head with a view to inducing a growth of hair. The impertinent assurance of the proprietors, who ask for advertisement and notice of their specious quackery in a medical journal speaks for itself.—ED., "M. P. AND C."]

Meetings of the Societies, Lectures, &c.

WEDNESDAY, FEBRUARY 20th.

ROYAL MICROSCOPICAL SOCIETY (20 Hanover Square, W.).—8 p.m.: Exhibition of Slides of Marine Zoological Objects lent by Mr. Flatters. Papers:—Mr. J. W. Gordon; An Early Criticism of the Abbé Theory. Mr. J. Murray: Some Tardigrada of the Sikkim Himalaya. Dr. E. Penard: On Some Rhizopods from the Sikkim Himalaya.

SOCIETY OF ARTS (John Street, Adelphi, W.C.).—8 p.m.: Mr. H. Williams: Cold Storage and Food Supply.

MEDICAL GRADUATES' COLLEGE AND POLYCLINIC (22 Chenies Street, W.C.).—4 p.m.: Mr. C. Ryall: Clinique. (Surgical). 5.15 p.m.: Lecture:—Dr. P. Horrocks: The Uterine Curette and its Uses.

NORTH-EAST LONDON POST-GRADUATE COLLEGE (Tottenham Hospital, N.).—2.30 p.m.: Cliniques:—Dermatological (Dr. Meachen), Ophthalmological (Mr. Brooks), Medical Out-patient (Dr. Whipham).

THURSDAY, FEBRUARY 21st.

NEUROLOGICAL SOCIETY OF THE UNITED KINGDOM (11 Chandos Street, Cavendish Square, W.).—8.30 p.m.: Annual General Meeting. Election of Officers. Presidential Address:—Dr. C. E. Beevor: The Distribution of the Arteries supplying the Human Brain.

MEDICAL GRADUATES' COLLEGE AND POLYCLINIC (22 Chenies Street, W.C.).—4 p.m.: Mr. Hutchinson: Clinique. (Surgical). 5.15 p.m.: Lecture:—Dr. G. N. Pitt: Associated Abdominal and Thoracic Disease.

NORTH-EAST LONDON POST-GRADUATE COLLEGE (Tottenham Hospital, N.).—2.30 p.m.: Gynæcological Operations (Dr. Giles). Cliniques: Medical (Dr. Whiting), Surgical Out-patient (Mr. Carson). 3 p.m.: Clinique:—Medical In-patient (Dr. Chappel). 4.30 p.m.: Lecture:—Dr. Corner: Mental Disorders associated with Pregnancy and Parturition.

ST. JOHN'S HOSPITAL FOR DISEASES OF THE SKIN (Leicester Square, W.C.).—6 p.m.: Chesterfield Lecture:—Dr. M. Dockrell: Fungous Diseases of the Skin: I., Tinea Circinata; II., Inbricata, Versicolor; III., Erythrasma; IV., Actinomycosis; V., Madura Foot.

FRIDAY, FEBRUARY 22nd.

BRITISH ELECTROTHERAPEUTIC SOCIETY (11 Chandos Street, Cavendish Square W.).—8 p.m.: Council. 8.30 p.m.: Paper:—Dr. S. Sloan: Some Physiological Effects of High Frequency Currents in Disease (illustrated by lantern slides and apparatus.

CLINICAL SOCIETY OF LONDON (20 Hanover Square, W.).—8.30 p.m.: Mr. R. Johnson and Mr. C. E. Reynolds: Case of Spinal Meningocele in an Adult Successfully Treated by Operation after Spontaneous Rupture had occurred. Mr. C. H. Fagge: Resection of the Jejunum and Colon for Carcinoma of the former.—Mr. T. H. Kellock: A New Method of Excising the shoulder-joint.

MEDICAL GRADUATES' COLLEGE AND POLYCLINIC (22 Chenies Street, W.C.).—4 p.m.: Mr. L. Lack: Clinique. (Throat).

NORTH-EAST LONDON POST-GRADUATE COLLEGE (Tottenham Hospital, N.).—9.30 a.m.: Clinique. Surgical Out-patient (Mr. H. Evans). 2.30 p.m.: Surgical Operations (Mr. Edmunds). Cliniques:—Medical Out-patient (Dr. Auld), Ophthalmological (Mr. Brooks). p.m.: Clinique:—Medical In-patient (Dr. Leslie).

Vacancies.

Leicester Infirmary.—House Surgeon. Salary £100 per annum, with board, apartments, and washing. Applications to Harry Johnson, House Governor and Secretary.

West Riding Asylum, Wakefield.—Assistant Medical Officer. Salary £150 per annum, with apartments, board, washing, and attendance. Applications to the Medical Director at the Asylum.

East London Hospital for Children and Dispensary for Women, Shadwell, E.—Medical Officer for the Casualty Department. Salary £100 per annum. Luncheon provided. Applications to W. M. Wilcox, Secretary.

Worcester County and City Asylum, Powick, near Worcester.—Third Assistant Medical Officer. Salary £140 per annum, with board, lodging, and washing. Applications to the Medical Superintendent.

London Open-Air Sanatorium, Pinewood, Wokingham, Berks.—Assistant Resident Medical Officer. Salary £100 per annum, all found. Applications to the Secretary, London Open-Air Sanatorium, 20 Hanover Square, London.

Royal Free Hospital, Gray's Inn Road, W.C.—Radiographer and Medical Electrician. Salary £100 per annum. Applications to the Secretary.

York County Hospital.—House Surgeon. Salary £100 per annum, with board, residence, and washing. Applications to Frederick Neden, Secretary and Manager, York.

Middlesex Hospital, W.—Resident Medical Officer. Salary £200 per annum, with residence and board in the Hospital. Applications to F. Clare Melhado, Secretary Superintendent.

Male Third Assistant Medical Officer.—Salary £150 per annum, with lodging, attendance, and washing. Applications to the Office of the Board, Embankment, London, E.C.

Leicestershire and Rutland Asylum, Leicester.—Second Assistant Medical Officer. Salary £120 per annum, with apartments, board, and washing. Applications to W. J. Freer, Esq., New Street, Leicester.

Shillelagh Union.—Medical Officer. Salary £130 per annum and £15 a year as Medical Officer of Health. Applications to J. Hopkins, Clerk of the Union. (See advt.)

Appointments.

BROWN, W. H, F.R.C.S.Irel., Consulting Surgeon to the General Infirmary, Leeds.

CARNELL, EDWARD, M.R.C.S., L.R.C.P.Irel., D.P.H.Irel., L.S.A., Medical Superintendent of the Newton Abbot (Devon) Joint Hospital District.

COLLINSON, HAROLD, F.R.C.S.Eng., Honorary Assistant Surgeon in Charge of the Patients at the Ida and Robert Arthington Semi-Convalescent Hospitals of the Leeds General Infirmary.

DOBSON, J. F., M.S.Lond., F.R.C.S.Eng., Honorary Assistant Surgeon to the General Infirmary, Leeds.

FORSYTH, R., M.D.Glasg., Certifying Surgeon under the Factory and Workshop Act for the Birstal District of the county of York.

GUBB, FLORENCE ERIN, M.B., B.S.Lond., L.S.A., House Surgeon at the Children's Hospital (East-End Branch), Sheffield.

HORSFORD, CYRIL, M.D.Edin., Laryngologist and Aural Surgeon to the London College of Music, Great Marlborough Street, W.

LANGMEAD, FREDERICK, M.D.Lond., M.R.C.P. Lond., Physician to Out-patients at Paddington Green Children's Hospital.

LEACH, J. C., M.D.Dub., Certifying Surgeon under the Factory and and Workshop Act for the Sturminster Newton District of the county of Dorset.

LORD, JOHN R., M.B.Edin., Medical Superintendent, London County Asylum, Horton, Epsom.

MACNAMARA, E. D., MB., B.Ch.Cantab., Physician to Out-patients at Paddington Green Children's Hospital.

OGG, THEODORE A. W., L.R.C.P. and S.Edin., L.F.P.S.Glasg., Medical Officer for the Parish of Rothes, Morayshire.

PEGLER, L. HEMINGTON, M.D.Edin., Laryngologist and Aural Surgeon to the London College of Music, Great Marlborough Street, W.

Births.

COSTELLO.—On Feb. 14th, at 76 Lower Mount Street, Dublin, the wife of T. B. Costello, M.D., Tuam, co. Galway, of a daughter.

PRINGLE.—On Feb. 14th, to Dr. and Mrs. Seton Pringle, 27 Lower Baggot Street, a son.

Marriage.

PITTS—COCHRANE-BROWN.—On Feb. 14th, at Christchurch, New Zealand, Arthur Gentry Pitts, F.R.C.S.Eng., eldest son of Robert Pitts, Merlewood, Sanderstead, to Dr. Edith Cochrane-Brown, only daughter of Thomas Brown, Esq., of Strathmere, Christchurch, New Zealand (late of Dundee).

Deaths.

NEEDHAM.—On Feb. 15th, at 19 Campden Hill Square, London, Charlotte, the dearly loved wife of Frederick Needham, M.D., in her 67th year.

PEAKE.—On Feb. 16th, at 228 Goldhawk Road, London, Rowland Mabbatt, only son of Solomon Peake, M.R.C.S., aged 21.

WARD.—On Feb. 17th, at Bournemouth, Austin George Ward, M.R.C.S.Eng., late of the Charity Organisation Society, aged 54.

THE CHILDREN'S HOSPITAL,
TEMPLE STREET, DUBLIN.

Applications for the position of Visiting Physician to this Hospital will be received by the Hon. Secretary, Medical Board, up to Feb. 28th, 1907.

THE MEDICAL PRESS AND CIRCULAR.

"SALUS POPULI SUPREMA LEX."

VOL. CXXXIV. WEDNESDAY, FEBRUARY 27, 1907. No. 9

NOTES AND COMMENTS.

L.C.C. Election. THE approaching election of members of the London County Council is exciting far greater interest than any previous one, and though it is encouraging to think that Londoners are beginning to concern themselves about the management of the wonderful city in which they live, it is much to be regretted that the polemics of the occasion should be so much embittered. The charges made against opponents are in many cases of the most invidious kind—even for municipal warfare—and when decisions of great pith and moment have to be taken, it is a thousand pities that the issues at stake should be overlaid with unworthy details. The County Council is the supreme health authority for London, and as the controlling and co-ordinating instrument of the policy of the Borough Councils, its importance is immense, so that medical men cannot but feel the responsibility of casting their lot in with one side or the other. From the hygienic point of view, the problem that overshadows all others at the moment is the housing question. The ground rents in the central parts of London make cheap and decent house accommodation impossible for the working-classes, and the only alternative is the erection of cottages in convenient situations in the outskirts, together with a rapid, cheap system of locomotion. Block dwellings in the inner ring are suitable only for the better-paid artizans, with no families or only one or two children, so that the question of traction—odd though it may seem—stands out as the most pressing sanitary question. The Council has already shown a strong sense of its responsibilities in this direction, and whatever may happen at the election nothing should be allowed to divert its energies from it in the future.

Education Pitfalls. THEN, too, the Council, as the Education Authority for the metropolis, has onerous duties to the rising generation, and it must realise the danger that it runs of centralising its authority on the Embankment. Few systems need more flexibility than educational ones, for the healthy child is the most variable factor in a world where change is the sign of life, and if under the Council administration becomes bureaucratic, the best intentions in the world will not suffice to atone for the certain disaster that will follow. So far the Council has taken some admirable steps with regard to providing medical inspection and nursing care for its pupils, and in this respect sets a wholesome example to the other public school authorities. An enterprising contemporary that feeds its readers largely on hollow sensations alighted on a pretty mare's nest the other day. The parents of a child under treatment for its eyes at a London hospital were advised, it was said, by the ophthalmic surgeon to keep the child from school, but through some bungling the child was compelled by the attendance officer to return to work, with the result that its eyes suffered much damage. This incident was placarded over London under the cheerful heading "Blind by order of the L.C.C.," and it was made the text from which to excite political prejudice against the Council. The *dénouement* was not long in coming, for a rival journal discovered that the child in question lived at Edmonton, a district which is not in the L.C.C. area !

"Deaf by Order of the L.C.C." THIS sort of stupid criticism of the work of the Council can only do harm, as it excites other people to indulge in equally wild accusations. At the last meeting of the Education Committee attention was called to a letter from a firm of employers who complained that six boys who came to them from the Council's schools, were deaf as the result of the swimming lessons now given them as part of their educational course. One of the Council's medical officers went down and examined three of the boys, and reported that there was no evidence that they were deaf even temporarily as the result of their swimming instruction; and that nothing of the kind had been heard of elsewhere. What an opportunity someone missed of getting up an agitation—"Deaf by order of the L.C.C." ! No, the policy of the Council wants much watching on the side of physical education and much encouragement. It can do nothing but harm to stir up blind animosity over imaginary grievances.

Bone-Setters' Ethics. WITH pomp and circumstance it is announced that Arthur Birch, the unfortunate jockey who was seriously injured at Gatwick last December, and who has been lying there ill ever since, has decided to fly in the teeth of the advice of Sir Victor Horsley, Mr. Lane, and his local medical attendant, Dr. Matthews, and to have himself transferred to London, that he may enjoy the advantage of the services of one Raby, a bone-setter. Birch is said to have been highly delighted when he knew he was to be moved, and "laughed at the grave fears of the doctors." We have no information as to the nature of the patient's injury, and, for all we know, his present condition may be represented in black colours in order that his subsequent cure may shine the brighter, but on the face of it the announcement strikes us as being in execrably bad taste, by whomever it was made. It has, however, had the effect of stirring up our friend, Mr. H. A. Barker, who fearing doubtless that he may be eclipsed by the new star, writes to the Press Association: "From the accounts I have of Birch's condition, I am of opinion that a manipulative or bloodless operation might be of the greatest service. The Hon. George Lambton was operated on by my predecessor, Mr. Atkinson, for a similar injury quite successfully some years ago." Mr. Barker's opinion is doubtless most valuable, but we do not follow his reasoning with regard to his "predecessor" and Mr. Lambton. Is it a necessary sequence that because his "predecessor" cured Mr. Lambton, whom he had seen, that Mr. Barker could cure Birch, whom he has not? It reminds us rather of the man who said he could not speak French himself, but that his cousin could play the German flute.

"Help."

RESEARCH and observation bring to light new diseases with disconcerting rapidity, and yet we appear to be far from having reached finality. For instance, a malady, new at any rate to ourselves and the inspectors of the Local Government Board, has arisen in our midst. Its name is "Help," but its clinical phenomena, its signs, symptoms, and portents, have so far not been described. Then only thing certainly known about it is the treatment, which consists entirely, so it seems, in the prescription of alcoholic stimulant. The disease was unearthed during the recent researches of an inspector of the Local Government Board into the books of the workhouse at Kedington (Suffolk), in the course of which he struck this remarkable entry frequently recurring in the column, headed "Nature of Disease," in which the illness for which alcohol was necessary for the inmates was inserted. The inspector, in his report, remarks that he is not sure whether "Help" is a disease or not. We can only say that if it is, in its usual manifestations it is not markedly contagious.

Union at Wimborne.

AT Wimborne recently the medical officer to the Guardians applied for a rise of salary. Considering that he enjoyed the princely emolument of £30 a year, out of which appliances and medicines had to be found, it is not surprising that the local Guardians should have stood as aghast as their predecessors when Oliver Twist proffered a similar outrageous request. The rise being refused, the medical officer resigned, and the post was advertised at a salary of £25, exclusive of appliances and medicines. The medical men in the town met together, discussed the situation, and decided that none of them would apply. So the Guardians have no candidates for the appointment. It is good to hear of such loyalty among members of the profession, for when the medical interests are not divergent they are irresistible. We shall be interested to notice the next step of the Wimborne bumbles.

LEADING ARTICLE.

THE MEDICAL INSPECTION OF SCHOOL CHILDREN.

THE progress of the Parliamentary coach, year in and year out, is to onlookers a spasmodic, an uncertain, and, at times, even a hopeless affair. Here it creaks and rumbles as if the whole structure were about to collapse in ruins, after the fashion of the wonderful "one 'oss shay." There it sinks to its axles in a slough of despond, or pauses for a prolonged period of renovation and repair. Yet on the whole its course is onward; and sometimes, when least expected, it speeds forward at a rapid rate, regardless of any difficulties of the road to be traversed. This metaphor might be applied with interest and advantage to the chequered career of public health legislation. From the outset of its scientific birth, almost, if not quite, within the memory of living man, it has had to struggle against enormously powerful vested interests of various kinds. Indeed, it may safely be asserted that not a few of the rocks ahead in practical sanitation depend upon obstacles of this kind. The medical officer of health, for instance, will never become a power in the land until his tenure of office is made independent of the local authorities, composed as the latter are of individuals whose interests in trade and in property are often opposed to the rights of the public as regards sanitation. Another cogent illustration is the vast capital sunk in farming and in dairies, which is vitally disturbed by the recent authoritative declaration of the Royal Commission that tuberculosis can be conveyed to mankind by infected meat and milk. Happily, however, many public health reforms do not involve any obvious interference with vested interests, although they involve necessarily some amount of sacrifice on the part of the ratepayers who have to foot the bill. Among the more hopeful of this sort of measure is the medical inspection of school children. There appears to be a fair prospect that a Bill for the furtherance of that object may be presented to the House of Commons by Mr. Walter Rea. Clearly it is a matter that deeply affects the medical profession as well as the nation. The principle of medical inspection was adopted in the Government Education Bill of last session by Mr. Tennant's amendment to clause 24, inserting a sub-clause providing for such inspection. There is little need here to enumerate the overwhelming case in favour of the systematic medical supervision of school children who will form the backbone of the next generation of our countrymen. If ever the problem of physical deterioration is to be strenuously handled, the first stages of the campaign must be carried out in our schools. The ultimate prevention of communicable disease, notably diphtheria, measles, scarlatina, and tuberculosis, hinges around this question. Incidentally the proper feeding, the physical culture, and the moral training of the rising generation are all woven into the warp and woof of this matter of medical inspection. So far as the general practitioner is concerned, more especially in the smaller towns and the rural districts, there are various points of practical administration upon which it is desirable that his mind should be made up and his attitude clearly defined without loss of time. In the large towns, it may be taken for granted that a whole time officer will, in most cases, be appointed. In other instances, where the school medical officer is permitted to engage in private practice, the situation becomes at once complicated with many possibilities of friction which need not be particularised. It may be as well to note, however, that the school medical officer is often called upon to examine teachers as to their health generally, and in case of sickness; further, to remind the medical profession that the proposal that is shortly to come before Parliament deals with the treatment as well as the medical inspection of school children. Indeed, so deeply are the interests of the medical profession concerned, that the whole matter is worthy of extended discussion. The General Medical Council is not likely, either by constitution or by inclination, to raise a voice in the protection of the profession. Almost the only body to whom medical men can turn with any hope of practical guidance and help is the Medico-Political Committee of the British Medical Association, and we learn with profound satisfaction that they are giving close attention to the subject. Under present circumstances, school boards all over the country contrive to secure a great amount of gratuitous medical service by way of certificates obtained without fee from general practitioners and from the honorary and paid medical staffs of medical charities.

CURRENT TOPICS.

Cerebro-Spinal Fever—A Warning Note.

THE epidemic of cerebro-spinal meningitis is rapidly spreading in various parts of the Kingdom. Especially alarming is the multiplication of cases in London, which, by reason of its unwieldy population, is apt to become the ready prey of any malignant infectious outbreak of the kind. The recent circular issued by the Local Government Board warns sanitary authorities to be on the alert, while at the same time it expresses the opinion that there is not at present any ground for apprehension. We fear that there is no strong foundation for such happy official optimism, and that the position is full of the gravest omen. Judging from the history of acute infectious maladies in general and still more from that of cerebro-spinal meningitis in particular, we are forced to the conclusion that the cases recorded in London and other parts of England are simply precursors of a widespread epidemic like those that are already occurring in Ireland, Scotland, and various parts of the Continent. Unfortunately our knowledge of the life-history of the specific micro-organism of the disease is inadequate to enable us to frame any trustworthy scheme of prevention. The first and last word of the medical profession in that direction, so far, is to insist upon the necessity of absolute attention to ventilation, cleanliness, and other details of domestic and personal hygiene. The fact that the malady, like typhus fever, specially attacks poor and overcrowded quarters, points to the first line of defence against its invasion. Londoners will do well to avoid the error of imagining with the ostrich that danger un-seen is danger averted.

A Chemist's Knowledge of Poison Regulations.

A CHEMIST named William Howell, of High Street, Peckham, has recently had the unpleasant experience of a prosecution by the Pharmaceutical Society of Great Britain, and the infliction of a mitigated penalty of 40s. and costs. Under the circumstances he may regard himself as fortunate for escaping so lightly from a serious position. The attention of the prosecuting society was very properly drawn to the case by the City of London coroner. A woman died of corrosive sublimate poisoning, and it was shown she had bought the drug from defendant, who was "a person unknown to him and not introduced to him." As a matter of fact, the unfortunate lady was an inmate of Bethlem Hospital, and had been let out for a day in charge of her father. In a fit of temporary insanity she purchased the corrosive sublimate and signed the poison book. The defendant chemist said the lady, although not actually known to him, was a customer. He was careful to ascertain that she knew all about the drug, and she mentioned the text-book she used in the study of photography. He was not aware that it was necessary for him to know or to be introduced to the buyer. The Pharmaceutical Society will surely have something further to say to a holder of their qualification who is so grossly ignorant upon a fundamental law of daily application in his business relations with the public.

Hospital Nurses and the Employers' Liability Act.

THE Employers' Liability Act apparently applies to hospital nurses, which means a simple revolution in the position of nurses, both in public and in private service. Should a nurse in the execution of her duties contract any illness or sustain any accident, she will be entitled, if we read the Act correctly, to indemnity. The responsibilities of medical charities will, in that event, be enormously multiplied, and will undoubtedly have to be covered by insurance. Recently, at Bangor Workhouse Infirmary Board, a nurse was reported to have contracted tuberculosis in the hospital. The question was raised by a guardian as to whether it was really tuberculosis, and, if so, whether it was "taken" in the Infirmary. These points suggest that in future medical practitioners will have to be extremely careful as to their grounds before publishing a diagnosis, and also in granting certificates or in making verbal statements about any given cases. Another curious result will be the possible effect of compensation upon existing nurses' insurance and pension funds, the contracts of which may require modification in view of compensation contingencies.

"Viewing" the Body and Parliament.

THE ancient ceremony of "viewing" the body at coroners' inquests, like many other legal customs, has long since lost its justification in expedience and necessity. The feeling of aversion to the practice is universal, and there should be little difficulty in passing into law the Bill to abolish compulsory "viewing" recently introduced into the Commons by Mr. Luke White. Himself a coroner, that gentleman represents the general feeling among his brother officials in urging this most desirable reform. There is no need to remind readers of the terrible nature of the ordeal that is thrust upon jurors by insisting upon this custom of feudal times. It is somewhat to be regretted, however, that the proposal is fragmentary, and does not form part of a wider scheme of reform in this ancient court. The present system works, on the whole, fairly well, but few even of its most ardent supporters would venture to assert it is incapable of improvement in the direction of suiting modern views and modern requirements.

Illegal Practice in France.

IN spite of an outward air of levity, our volatile neighbours on the other side of the Channel are wont to treat vital issues in the most logical and serious of fashions. The crusade against quackery is carried on in Great Britain by the medical journals, aided by the fitful and capricious action of the police. In France, however, the lot of the unlicensed practitioner is apt to be far from a happy one. A gentleman of that kidney named Thomas Xambo has recently been convicted in the Tenth Correctional Chamber of the Department of the Seine for illegal practice. The prisoner was charged with having treated a relative of the plaintiff for a trouble of the ankle, making several incisions, with the result that the leg had to be amputated by a duly qualified surgeon. The prisoner, once a student in pharmacy, was sentenced to eight months in prison, also to pay a 2,000 fr. fine and 1,000 fr. to the Société des Médicins de Paris. This short shrift to a dangerous class of social parasites might be copied with advantage on our own side of the Channel.

The English Royal Colleges and Diplomas for Women.

IT is now many years since women stormed the portals of the medical profession in the Royal College of Surgeons of Edinburgh. Some years later the Irish Colleges threw open their qualifications to women. The English Colleges, both of Surgeons and Physicians, however, have always adopted an unfavourable attitude towards the admission of women to their examinations and diplomæ. In the year 1895 they seriously discussed a petition praying for the abolition of the sex distinction in the candidates for the diplomas of the Colleges. The petition was rejected both by the Surgeons and by the Physicians, but not by large majorities, and there the matter has rested until lately. The subject has recently been brought to the front, however, by the appointment of a committee of the Surgeons to consider the question afresh. From all that we can gather, it seems to be within the bounds of probability that the women may carry this as they have previous positions. Moreover, there is some rumour that even so highly conservative a body as the London College of Physicians may surrender in a similar fashion. Indeed, as the two institutions examine by means of a conjoint board, the consent of both would be necessary to enable women candidates to sit for the ordinary diplomas, and it is hardly likely that the College of Surgeons would admit candidates for the F.R.C.S., whom the College of Physicians would decline to allow to sit for the M.R.C.P. However, the mere fact that such changes come within the range of practical college politics throws a gleam of hopefulness upon the situation as regards much-needed reform in other directions.

The Royal Society of Medicine.

THE amalgamation of London Societies has now settled upon a name, which is both dignified and imposing. As "The Royal Society of Medicine" we wish the new body a long and distinguished career. It is interesting to recall the fact that similar proposals to join forces were put forward nearly forty years ago. There are twenty-five societies in the Metropolis that would be eligible for inclusion, and of these twelve have agreed to join, four are willing to join conditionally, and of the remainder five have definitely declined the invitation. It is interesting to note that one reason urged against the selection of the title of "The Royal Academy of Medicine" was that the abbreviation R.A.M. is already popularly allotted to the Royal Academy of Music.

The Health of Belfast.

As has been expected for some time, the Government has appointed a Commission to inquire into the health of Belfast. The terms of reference are of the widest possible character, including "any subject that bears directly or indirectly on the health of Belfast." Much interest has been roused on sanitary matters in Belfast during the last few months, and several candidates were returned to the Corporation on the "Public Health Ticket" at the recent elections. The proceedings of the Commission will therefore be watched with close interest by the citizens at large, an interest greatly increased by the events of the past few weeks. As is well known, the city is at present being visited by epidemic cerebro-spinal meningitis of a virulent type, the disease showing no signs of diminution. At the same time, typhoid fever has broken out and the infection has been traced by Professor Symmers to the water supply. While the Commission, therefore, is likely to have many serious questions to decide, we cannot help expressing wonder at its *personnel*. Only three of its five members are medical men, and distinguished as the other gentlemen may be in their individual spheres, we cannot but think that an inquiry into the health of a community is for the most part a

matter for medical men. The Commission should, we think, have been mainly constituted of active working medical officers of health; only one of the members, Dr. Chalmers, of Glasgow, is a medical officer of health. Moreover, for the present condition of affairs two bodies are responsible, the Corporation of Belfast and the Local Government Board of Ireland. It seems strange, therefore, that two of the five commissioners should be officials of the latter body.

Carlyle and Women.

AN unpublished letter from Carlyle is always likely to be more or less of an event, and such a letter of his, written in 1871, was published in the *Scotsman* last week. For the medical profession it possesses particular interest from the views therein expressed by the sage on women and medicine. After expressing his opinion that the "true and noble function" of a woman was to be a good wife, housewife, and mother, he goes on to say that "If a woman miss this destiny, or have renounced it, she has every right before God and man to take up whatever honest employment she can find open to her;" also that medicine is not intrinsically unfit for women, because they have virtually practised medicine and surgery, to say nothing of nursing, on their relatives and friends since the world began; "in much more sound and earnest ages than ours," as he characteristically puts it. Then he continues: "Two things are not doubtful to me in this matter. First, that women —any woman who deliberately so determines— have a right to study medicine, and that it might be profitable and serviceable to have facilities, or at least possibilities, offered to them for so doing; and second, that, for obvious reasons, female students of medicine should have female teachers, or else an extremely select kind of men, and, in particular, that to have young women present among young men at anatomical classes, clinical lectures, or generally studying medicine in concert is an incongruity of the first magnitude, and shocking to think of to every pure and modest mind." Yet in thirty-five years this "incongruity of the first magnitude" is a commonplace, or nearly so. Is it because there has been difficulty in finding "the extremely select kind of men," or that the selection has proceeded on the usual Darwinian lines?

Burial Law Reform.

WHEN, we wonder, is the question of reform in the law relating to the certification of deaths and to burials going to be taken up seriously? There is no sort of mention of it in the King's Speech this session, and no indication that the necessity for it is recognised. Yet every year the bodies of numbers of persons are buried without certificate, and the law still requires no burial order for still-born children, or children alleged to be still-born. In other words, every year numbers of children are murdered soon after birth and buried as "still-born." Only last month at Walsall an inquest was held on a child who had died four hours after birth. The midwife put the body in a dry-soap box with a view to burial, and would have actually buried it, if the police had not had information which caused them to seize the box. The mother denied knowing anything about the manner of the child's death, and the medical witness testified to there being some marks on the face. The jury found eventually that the child had been suffocated in bed by a hand being placed over the mouth, but by whom there was no evidence to show. The midwife was censured. The jury were horrified to find out that any number of still-born children could be buried in a cemetery by the bearer of the body merely answering a few questions, and they registered their view that the law needed alteration. So, indeed, it does, but as there is no political capital to be made out of dead babies in England, the question is likely to have to take a back seat for a great many sessions yet to come.

PERSONAL.

DR. GEORGE CARPENTER lectured on February 20th at the Institute of Hygiene on "The Rearing of Children."

DR. A. J. RICE-OXLEY has been appointed a Physician in Ordinary to her Royal Highness Princess Henry of Battenberg.

ON February 20th, at a meeting of the Elective Committee of Chester Infirmary, Mr. W. Henry Dobie, M.B., C.M.Edin., M.R.C.S.Eng., was appointed to the position of honorary surgeon, vacated by the resignation of Mr. James Taylor. Mr. Dobie has been for ten years honorary assistant surgeon to the infirmary.

DR. R. G. ALEXANDER has intimated his resignation as honorary physician to the Halifax Royal Infirmary, to which post he was elected in 1886 as successor to his father, the late Dr. William Alexander, who had held that position since 1840.

AT the meetings of the Poor Law Commission held last week the following medical witnesses were examined:—Dr. James Allan, medical superintendent, Leeds Union Infirmary, Dr. Spottiswoode Cameron, medical officer of health, Leeds, and Dr. Scurfield, medical officer of health, Sheffield.

PROFESSOR RONALD ROSS, F.R.S., will lecture at the Royal Sanitary Institute on Friday, March 1st, on "Points of Interest connected with Tropical Sanitation."

DR. F. S. TOOGOOD will give an address at the annual general meeting of the Association of Certified Dispensers on Thursday, February 28th.

Sir JOHN MOORE, M.D., visiting physician to the Meath Hospital, has been elected president of the Irish Medical Schools' and Graduates' Association.

THE Gillson Scholarship in Pathology of the Society of Apothecaries of London has been awarded this year to Francis Arthur Bainbridge, M.A., M.D.Camb., D.Sc.Lond., M.R.C.P.Lond., of Guy's Hospital.

MR. LUKE WHITE, M.P., who recently introduced into Parliament a Bill to abolish "viewing" of the body at inquests, is the only coroner who couples that office with a seat in the Commons.

MR. HERBERT SAMUEL, M.P., Under-Secretary for the Home Department, intends to re-introduce at an early date, with some modifications, the Poisons and Pharmacy Bill, which will ultimately settle the vexed question as to the use of the title of chemist and druggist by trading companies.

A Clinical Lecture

ON

THE TREATMENT OF CONCOMITANT CONVERGENT STRABISMUS.

By J. B. STORY, M.D., F.R.C.S.I.,

Surgeon to the Royal Victoria Eye and Ear Hospital; Ophthalmic Surgeon to Dr. Steeven's Hospital, Dublin.

The subject of Strabismus is one upon which it is very desirable that the student should have correct views, as when established in practice, no matter what his or her speciality may be, advice will be sought by anxious parents for the treatment of this deformity in children's eyes.

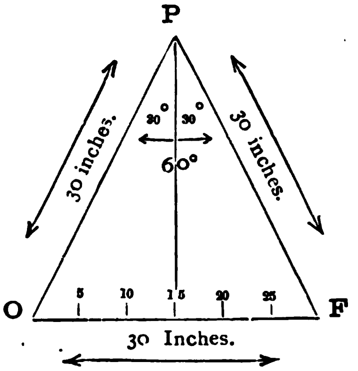
The questions asked by the parents will probably be (1) Is there a cast? (2) Can it be cured? (3) When should it be treated, or, perhaps, will the child grow out of it? Now, the answer to the last question is the most important of all, and that answer is, that *the deformity should be treated at once, and the earlier the better.* That the child may grow out of it is not impossible, but is so far from being probable that it should never be entertained by any reasonable person, for theory and experience are at one in maintaining that these deviations do not get better, but for a time grow worse, and then remain permanent.

Until a few years ago it was very usually held that surgical interference in Strabismus should be postponed till the child was five or seven years of age, and this opinion you will find in many text-books, and it is acted on by many medical men all over the country. Nothing can be more harmful than that cases of Strabismus should be left to nature, as this opinion leaves them, during the first six or seven years of life. Treatment should be commenced as soon as the cast is observed, and as regards operation it should be performed as soon as the effect of treatment shows that operation is necessary.

I have already answered the second question inferentially. The deformity can be cured, and now we come to the first: "Is there a cast in the child's eyes?" This is ascertained by getting the child to fix some object (a bright object like the ophthalmoscope mirror in the case of a very young child) and observing if the two eyes appear to be directed at the object. If one eye appears crooked, slip your hand before the straight eye, and if a movement of the crooked eye occurs, Strabismus is present. This diagnosis is substantiated by observing at the same time that the originally straight eye has turned crooked behind your covering hand. The deviation of the usually crooked eye is termed the Primary Angle, and that of the usually straight eye, when you have excluded it from fixing the object and the crooked eye is fixing, is termed the Secondary Angle.

As a matter of clinical experience these two angles are equal in all cases of Strabismus properly so-called, and it is in the equality of these angles that Strabismus differs from Paralysis.

When making this examination you may find that the crooked eye does not fix at all, or looks to the side of the object when you cover the good eye. You then conclude that it must be more or less Amblyopic. This, however, is no bar to treatment, and in sufficiently young children no bar to cure. Before commencing treatment you must note the amount of the squint—in more technical terms the size of the angle of deviation—and this is a quantity that none of you will have any difficulty in measuring if you adopt the simple plan that has been proposed by Priestly Smith. The only instrument required is a tape measure. The one I use is thirty inches in length, and of course only determines the angle of squint for a fixation distance of thirty inches. This is the method. I seat myself in front of the patient thirty inches between his eyes and my own right eye and reflect light by an opthalmoscope mirror into his eyes. One of these eyes is straight, and I see the reflex of the ophthalmoscope in the centre of the pupil of that eye. The other eye is crooked, and the reflex is seen to the outer side of the pupil, perhaps close to the periphery of the cornea. I now move my finger towards the side of the crooked eye, keeping my own eye still thirty inches distant from the child's eye, and also keeping my finger the same distance from it, and persuade the child to look at my finger. As the good eye follows my finger towards the side of the crooked eye, the latter moves also in the same direction, and a time comes when the crooked eye arrives at the point from which the good eye started—viz., pointing straight at my eye and the ophthalmoscope, and I know this by observing the reflex of the mirror in the centre of the pupil. I then measure the distance my finger has travelled from my eye along the tape, and I record one degree of strabismus for each half-inch of that distance.



In the triangle I have drawn on the board, the patient's eye is at P. the observer's eye at O, and the observer's finger has moved along the line from O to F.

You will say at once that I have not measured either the primary angle of squint in this case, or the secondary. And I admit that you are correct. What I have measured is the angle through which the good eye has happened to rotate during the time that the crooked eye rotated from some unknown position to the point at which the good eye was originally fixed. This angle, however, is equal to the other angles, so that in measuring it I have measured both the primary and secondary angles. I am speaking from a purely clinical "practical" point of view, for neither the ophthalmologist nor the mathematician can accept the method as perfect.

You will understand why I say that each half-inch measured corresponds to one degree of strabismus from the following considerations:—If my finger has travelled, let us suppose, the distance of thirty inches along the tape measure before I perceive the reflex of my mirror in the centre of the pupil of the crooked eye, then you see I have obtained an equilateral triangle, one of the angles being at the patient's eye. There are thirty inches between my eye and the patient's eye, and between my finger and the patient's eye. Each angle of such a triangle is two-thirds of a right angle, or sixty degrees. If my finger is but half that distance from my eye, the angle at the patient's eye is halved; it is then thirty degrees, or if the distance is but one-sixtieth of the original thirty inches the angle is just one-sixtieth of the original angle—viz., one degree.

It is obvious that, mathematically, this calculation is not quite correct, but the errors of calculation are so very much smaller than the unavoidable errors of observation that they may be neglected. There are other methods of measurement that are more perfect from a mathematical point of view, but they are all subject to much the same errors of observation, and no method gives accurate results unless the crooked eye has such good power of fixation that the observation can be corrected by an exact knowledge of the true position of that eye.

There are defects also in the method from a purely ophthalmological point of view, some of which are probably familiar to you. First, the centre of the pupil does not always coincide with the line of fixation. This can be observed in the straight eye. It is seldom the reflex of the mirror is seen in the centre of its pupil when it is actually looking at the ophthalmoscope. What we attempt to do in such a case is to get the mirror reflex in a corresponding position in the pupil of the crooked eye, and then assume that this eye is directed straight at the mirror.

In another respect you will also observe that my examination is incomplete, for I have only measured the angle of squint for a fixation distance of thirty inches. Who knows that it is not greater or less at other distances? As a matter of fact, it usually is, and in cases where the child is old enough to permit these measurements to be made with any approach to accuracy, further examination should be undertaken.

This would take up too much time at present, and we shall proceed to the matter of treatment.

Now the method of treatment depends upon the theory we hold of the etiology of strabismus. Is it a purely "mechanical" deformity caused, for instance, by a congenital shortness of a muscle? All theories of this description are now quite abandoned. Is the deformity due to defective vision in the crooked eye? Although defective vision is admitted as one of the factors, this theory is also abandoned, as it seems to be pretty well established that the strabismus is more to be regarded as the cause of the amblyopia than the converse.

The theory that is most widely held at present is that CONVERGENT STRABISMUS IS "A DISEASE OF INNERVATION." The visual centres fail to control the act of convergence, and the act becomes excessive, just because it is uncontrolled. This failure of control depends upon some derangement of the visual apparatus, central or peripheral, which need not concern us just at present. Hypermetropia is a predisposing cause, and once a squint occurs the disorder is confirmed by the suppression of the retinal impressions in the squinting eye.

FUSION FACULTY.

The normal man possesses, as you all know, a faculty for fusing the two images formed upon his two separate retinæ into a single image. Otherwise, we would see all objects double. A defective development of this faculty is present in every case of strabismus, and is to be regarded as essentially the cause of the deformity. Without this faculty, what we call binocular vision cannot exist, and if it is present and a deviation, a squint, exists, diplopia must be present too. Diplopia is never complained of by squinting children, though possibly it exists when the squint first appears. At that early age the child cannot tell us. Or, again, the squint may come on before there is any definite fusion faculty in existence. The fusion faculty has, unlike the poet, to be made, for it is certainly not born with us. That the new-born baby does not possess it is obvious to the most casual observer. Other faculties, other centres, are also imperfect, undeveloped, at birth, and the eye itself is even anatomically an incompletely developed organ.

As regards the fusion faculty, Worth holds that it normally attains its full development before the age of six. Up till that age there is, then, some chance of improving an imperfect faculty, or even of developing one apparently non-existent, but after that age the attempt is probably hopeless, and a perfect cure—that is, the establishment of binocular vision—is impossible. No cure is really perfect unless binocular vision is attained, and this cannot be attained in many cases. But a cosmetically perfect cure is always possible, even when the crooked eye is practically blind.

There are many points that ought to be determined before making a prognosis or undertaking the treatment of a case. In very young children all of these cannot be determined, but we should deal with as many as we can:—

(1) Is the squint unilateral or alternating?

(2) Is it continuous or periodic, and if the former, constant or varying in amount?

(3) What is the physical condition of each eye? Perhaps there may be a patch of central atrophy in the retina.

(4) What is the functional condition of each eye—viz., vision, field of vision, refraction, fixation power of crooked eye, which has been already mentioned, the possibility of eliciting diplopia by prisms or coloured glasses, &c. A good fixation power and the possibility of seeing double are favourable prognostic signs.

(5) What power have the muscles to rotate the

eyes in different directions—that is specially their lateral movements.

TREATMENT.

Having established as many of the above points as the case permits, or as we think necessary, the next thing to do is to try what change in the condition can be produced by paralysing the accommodation. This is done, of course, by the use of atropine, but if the squint is unilateral and more especially if the crooked eye has no proper power of fixing, the atropine must be used only in the good eye. This is most important, as by doing this we diminish the sharpness of vision in this good eye, and induce the child to make use of the crooked eye in preference. We still further throw the crooked eye into use by getting the nurse or mother to put a pad or bandage over the good eye for some definite period two or three times every day. The most satisfactory result you can have from the above treatment is when the mother reports to you in the course of one or two weeks that " the bad eye is cured, but, unfortunately, the cast has gone into the good eye." This proves that there is good power of sight and fixation in the originally crooked eye. We now put atropine into the good eye also, and expect, what does not always happen, that the two eyes will become straight. If they do, the wearing of glasses (to correct the hypermetropia or astigmatism that is nearly universally present) will probably effect a permanent cure. Or atropine may have to be used for some weeks longer, along with the correcting glasses. If the child is quite too young to wear glasses at all, we can only continue to use atropine in moderation until we can put on the glasses.

The immediate cure effected by atropine and glasses is not always permanent—by which I mean that the cast returns when the atropine is discontinued. In these cases atropine may be used for several months without danger, and glasses worn that over-correct the hypermetropia—in fact, render the eyes artificially myopic.

The solution of atropine I employ is usually the liquor atropiæ sulph. of the Pharmacopœia, but in very young children I use only half the strength. One drop in the eye twice a day is as much as is ever required, and in cases where a long continuance of the mydriatic is indicated, one drop every second day may be sufficient. You should be careful to avoid toxic symptoms in young children. They mostly come from the solution passing down the nasal ducts into the nose and pharynx. You will prevent this happening if you have the eye dried with a handkerchief immediately after the drop has been instilled.

STEREOSCOPIC EXERCISES.

When we have got the eyes straight by the treatment already described, or, indeed, before this happy result is obtained, we attempt to develop and improve the dormant power of fusion by stereoscopic exercises. There are many instruments devised for this purpose. The one I employ habitually, and which I get my patients to use at home, is the stereoscope of Hallwach. It is so cheap that persons of moderate means can afford to buy it. It differs from the ordinary stereoscope in being capable of adaptation to any degree of squint. In the ordinary stereoscope only those who have no squint can fuse the two pictures. In Hallwach's, fusion can be effected even if there is a squint of fifty degrees. Different pictures are employed according to the amount of binocular vision present in the case. In the first type, where only what is termed simultaneous macular perception is present (that is, where the child perceives that there is a picture before each eye—viz., can see the two pictures at the same time; for in consequence of the suppression of the image formed in the crooked eye, many cases cannot see the picture formed in that eye so long as the good eye is open), pictures are used like this of a bird in one picture, and a cage in the other. We try then to get the child to see the bird and the cage at the same time, and then to get him or her to see the bird actually in the cage. Other types of pictures are like this : a dog trying to jump up a pillar in one picture and a cat standing on the top of a pillar in the other. The child should see the two pillars as one, with a cat on the top and a dog trying to jump up. None of the pictures of this type elicit true binocular vision—that is, the perception of depth, solidity, distance. When this is attained the cure is perfect, but we have to use pictures of another type to demonstrate the existence of perfect binocular vision. When the child fuses any of these pictures, we try to increase his or her range of fusion by altering the angle of the stereoscope, so that the eyes have to be more converged or diverged to keep up the fusion.

There are other instruments devised for the purpose of developing and exercising the fusion faculty, of which the amblyoscope of Worth is perhaps the most perfect. It is an instrument which is employed by the surgeon himself, and not suitable for home use in consequence of its relatively high price.

The treatment described can be carried out by any medical man, and does not require the attention of a specialist in ophthalmology, though naturally the family doctor will procure the collaboration of an oculist when possible. When, however, this treatment has been given a sufficiently long trial without producing a cure, a specialist is, in my opinion required in order to determine if an operation is necessary, and if so what operation.

I shall not enter into this matter in the present lecture, not alone on account of want of time, but also on account of the impossibility of laying down definite rules either as to the length of time treatment should be carried on before having recourse to operation, or as to the particular operation to be done in a given case.

Each case must be judged according to its own special idiosyncracies.

NOTE.—*A Clinical Lecture by a well-known teacher appears in each number of this journal. The lecture for next week will be by Patrick Dempsy, F.R.C.S.I., M.R.C.S.Eng., Surgeon for Diseases of the Throat, Nose and Ear, Mater Misericordiæ Hospital, Dublin, on " Empyema of the Maxillary Antrum."*

MEDICAL MEN AND THE POOR LAWS.—At the meetings of the Royal Commission on the Poor Laws on January 28th and 29th, evidence was submitted by Dr. James Niven, Dr. Barlow, Dr. Meredith Young, and Dr. J. Milson Rhodes; and by the following witnesses representing the British Medical Association : Dr. J. Macdonald, Taunton ; Dr. H. Langley Browne, West Bromwich ; Dr. Ford Anderson, Hampstead ; and Mr. J. Smith Whitaker, medical secretary.

ORIGINAL PAPERS.

THE GYNÆCOLOGY OF TO-DAY AND FIFTY YEARS AGO. (*a*)

By W. D. SPANTON, F.R.C.S.

The tendency of recent years has been to specialize in every department of science. Hence it comes to pass that the modern gynæcologist is acknowledged to be one devoted rather to the special maladies of women than to obstetrics. More often than not, indeed, the gynæcologist does not practise obstetrics at all, any more than the pure physician does surgery. He finds, in fact, quite enough to do in his own department, which is mainly surgical. The general practitioner, especially in remote districts, must necessarily combine both offices, so perhaps a few remarks on this practical side of the question may not be out of place.

Mr. B. Jessett told us recently, in his interesting story of the history of ovariotomy, some of the difficulties which were encountered by ovariotomists in its early days. I recollect seeing Spencer Wells and Baker Brown operate in the early sixties, and at that time the operation was looked upon as quite an event, especially in a general hospital. This is hardly to be wondered at, with the mortality which then prevailed. It requires a considerable amount of courage to perform an operation which has been denounced from the medical pulpits as unjustifiable and murderous. The same denunciations have been made concerning many surgical procedures, notably those for the radical cure of hernia, and it is a significant fact that opposition came chiefly from those metropolitan teachers whose knowledge of anatomy and the principles of surgery ought to have availed to prevent them With the exception of John Wood in London, all the early successful work in this direction was done by provincial surgeons, notably by that sound surgeon, Sir W. Mitchell Banks. But this is a digression.

Let us consider for a moment the attitude of the profession half a century ago, with regard to some other affections of women which are matters now of everyday occurrence.

Take, for example, the excision of the cervix uteri for various forms of cancer. We are told that this operation, which had been performed repeatedly on the Continent, had been very rarely done in this country. Lisfranc was at this period its foremost advocate, and his results may be gathered from the fact that out of 19 private cases, four died within 24 hours, and 12 had an immediate relapse. In another series we find, out of 9 patients operated on, 6 had frightful hæmorrhage, three of whom died within 24 hours. "Such facts were held to deter the most hardy from attempting this fearful operation." (*b*) Another writer, Dr. Montgomery, declared his "conviction of its almost universal impracticability, and of its utter inutility." Dr. Robert Lee also stated "it must appear unnecessary to pass a sentence of condemnation upon the practice of removing the uterus, either wholly or partially, when afflicted with malignant disease. The operation appears to be equally cruel and unscientific." This was the leading text-book of that period. But, in spite of these pronouncements, Professor (afterwards Sir) James Simpson had then operated on eight cases, only one of whom had died, and a few single cases of success are recorded by other operators.

One can hardly be astonished at the dread of this operation when we read of the methods of procedure. Dupuytren used a kind of spoon with a cutting edge, "cullier tranchante," by which the cervix was gouged out. Various other mechanical contrivances of an elaborate character were employed by other Continental surgeons, but in none of them was any attempt made apparently to amputate in what we now consider a surgical manner—by making flaps and properly securing the vessels. To restrain hæmorrhage plugging alone seems to have been resorted to, which failed more often than not. Here, as in so many other matters, it was not until the true principles of clean surgery were adopted that any real success was attained. No one now ever anticipates a fatal result from a properly conducted operation for excision of the cervix uteri.

Then we come to extirpation of the whole uterus. In the presence of so many who have had far larger experience of this operation than I have had, I wish to speak cautiously; but certainly the immediate results of the operation as practised now are abundantly conclusive as to its safety. How far it is curative when performed for malignant disease may be still an open question. At the date I am referring to, however, it was proscribed even more rigorously than the operation limited to the cervix.

Vaginal hysterectomy for prolapsed uterus, associated with many conditions, such as inversion, polypus, and so on, had been successfully practised by many obstetricians then, some being done in a very crude fashion. But the deliberate removal of the uterus when *in situ*, for uterine tumours, had been only then just begun, mostly in single instances, among which we find one by our esteemed Hon. President, Dr. Barnes. At that date there is a record of only 19 cases, 6 of which belong to British surgeons. "Of these no less than 16 died in consequence of the operation, one only as late as the fourteenth day, the others mostly on the following or third day at the latest; some in a few hours or even a few moments after the operation."(*a*) Velpeau stated that this operation had been performed 21 times in 20 years, not one of which had been permanently cured. It was about this time, when the fatality of vaginal hysterectomy was so alarming that Dr. Clay, of Manchester, and Dr. Köberle, of Strasburg, ventured upon abdominal hysterectomy. Dr. Clay's first patient, where he also removed both ovaries, recovered.

When we remember that the usual method employed then was either to use the ecraseur or one or more ligatures which were left to slough away, the time occupied being from three weeks to two months, no surprise need be experienced at the extremely large proportion of fatal cases. With modern methods, in which the ordinary principles of surgery are fully carried out, the operation has been rendered, as we are all aware, a comparatively safe one, and of immense advantage to those unfortunate women who are, without it, doomed to a most pitiable, lingering condition of intense suffering and certain death.

Now we come to abdominal hysterectomy, which, as I have said, was first done successfully by Dr. Clay in this country. Dr. Blundell, with his usual sagacity, wrote about this time:—"Might not the womb be taken out above the symphysis pubis? . . . . The effects of these malignant ulcerations are so deplorable that I think the propriety of extirpating the womb in these cases ought certainly not to be lost sight of." But up to the period of his writing this most valuable suggestion, I can find a record of only four cases, the first being in 1825. Even the bold and sagacious Sir James (then Dr.) Simpson says in 1860:—"Judging of the operation *a priori*, we should regard the operation as unjustifiable, and experience seems only to confirm the judgment. . . . I have no hesitation in saying extirpation of the uninverted uterus is such a hazardous operation that it should be rejected as an utterly unjustifiable operation in surgery."(*b*) Dr. Churchill tells us he finds "it is really difficult to find adequate reasons in its favour, except the repugnance which everyone must feel to give up entirely the hope of affording relief from the most agonised sufferings to which the female sex is exposed." This sentiment, so eloquently expressed, is, I venture to believe, the one which animates us to-day, and is the mainspring of the endeavours which have been made in succeeding years to render such operations so safe, and bring them to such perfection, as to warrant us in not only ad-

vising, but persuading our patients to submit to them.

Concerning inflammatory affections of the ovaries, I will quote some extracts from a leading text-book of the period I am referring to:—"Inflammation (of the ovaries) may spread to the broad ligaments and the peritoneum. . . ." And the author naïvely adds:—"It is scarcely necessary to mention that this complication compromises the safety of the patient. . . . The formation of matter is a frequent termination of both acute and chronic ovaritis. . . . The abscess may burst into the peritoneum and cause fatal peritonitis, or it may terminate in gangrene, which will not be discovered until after death," and so on. Then follows the treatment—*secundum artem* of that period, including "antiseptics and chlorides internally, with blisters and camphorated frictions externally," where gangrene is feared. Then it concludes:—"Failing in all these remedies, it has been proposed to cut down upon and extirpate the ovary, but no one has been foolhardy enough to reduce this suggestion to practice." (*a*)

It is quite evident that many of the cases referred to as abscess of the ovary were salpingitis, a subject dismissed in a few lines without any hint of surgical interference. What a change has taken place since that was written! The dread of meddling with the peritoneum which prevailed was, no doubt, one chief reason for the teaching of that day, and those who have taught us not to fear but to utilise the peritoneum have done more, perhaps, to advance abdominal surgery than any other workers. What would be said now of a surgeon who knowingly left an ovary, or Fallopian tube, to set up fatal peritonitis or gangrene without an attempt to relieve it by surgical means?

In looking through the records of early gynæcology. one cannot help being impressed by the fact that, for a long period, most of the pioneer work was done by the Continental obstetricians and surgeons, and in most of the instances I have referred to previously we find ourselves following rather than leading. This is not so now, I quite believe, and our backwardness may be attributed in some measure, perhaps, to the innate modesty of Englishmen—and English gynæcologists in particular—for I can see no other reason to explain it.

In connection with this part of my subject, it is only just to refer to the very important work accomplished by the women obstetricians and gynæcologists of that time. If we take, for instance, the practical records of Madame Bovin, we shall find there information of the most valuable kind, which had an important influence on subsequent practice during the evolutionary stage of modern gynæcology. That indebtedness to women gynæcologists has not diminished as time has progressed, and we are rejoiced to find among our Fellows some whose knowledge and technical skill has never been surpassed.

The time has surely arrived when the scientific teaching of the department of gynæcology, which has been long recognised and carried out in the provinces and in special hospitals, should be adopted in a whole-hearted manner by all the Metropolitan Hospital Schools.

I hope the time will come when more liberal ideas will prevail, and a sort of extramural practice will occupy its proper place, to be recognised on its merits by the examining boards. It is much to be desired that attendance on such a special course should be made compulsory, concurrently with that of obstetrics. Diseases of children might very well be kept apart

To return to my text. I remember the time when fistulæ, rectovaginal and vesicovaginal, were common enough, and the brilliant efforts of gynæcological surgeons at home and abroad were beginning to be recognised. Now such affections, thanks to the better teaching of obstetrics, with the scientific use of forceps, are becoming rare, and there is happily less scope for the surgeon in that direction. On the other hand, we meet more frequently with cases of ruptured perineum since the use of forceps has become general, and it is due largely to the teaching and practice of Lawson Tait that this misfortune has lost its terrors. The general practitioner who meets with a case of ruptured perineum now (and I pity the man who tells you he never had a case), if he be at the same time conscientious and capable, sets to work to repair the damage immediately. Hence it is that only more severe cases come under the care of the operating gynæcologist. This is a thing to be thankful for, and is, I believe, the direct result of the teaching of modern gynæcologists. Happily it has now become a well-recognised rule that no surgeon can be held liable for accidents, such as the rupture of a perineum, especially in primiparæ; while he is liable, both legally and morally, for pecuniary compensation on the one hand, and just opprobrium on the other, if he fails to recognise, and does not at once adopt, the necessary measures to cure such a condition.

Take as another illustration of the enlightenment of the ordinary medical attendant by the advanced teaching of the gynæcologists those varied conditions of endometritis set up by fœtal remains left behind after abortions especially. I remember many years ago a case of this kind, at the time I was assistant to the late Sir W. Priestley, when such conditions were rarely recognised. A patient suffering from a putrid discharge, with general septic condition, was admitted into the cancer wards under one of his colleagues as a well-marked case of cancer. Sir W. Priestley was asked to see her, dilated the cervix, found a small piece of old placenta, removed it, and the patient was soon well—rather to the chagrin of the surgeon who failed to recognise it. Now I venture to think most men are so much better informed that a mistake of this kind is far less likely to happen.

There are some points in this relation which are worth a moment's consideration, notably the difference in the results in private and hospital practice. This is an old story, and I know that opinions differ with regard to it, but no one has ventured yet to assert that the results, both as to fatality and speedy recovery, are not vastly better in private than in hospital. There are many reasons for this, especially the personal element. In hospital work, the after-treatment of cases must necessarily fall upon those who have had less experience than the operator himself—there are many loopholes for the introduction of adventitious elements of danger. The surroundings of the patient are less restful to the nervous system, and, with many, this is a matter of vital moment. On the other hand, in private, the surgeon usually sees the case through himself, superintends each dressing, directs personally every detail, chooses his own experienced nurses, and, above all, is enabled to ensure for his patient that quiet and seclusion which tend so greatly to speedy recovery. The results, so far as my practice is concerned, differ greatly in the two classes of patients—so much so that, with regard to some operations, such as breast excisions, I have never had a fatal case in private among a total of about 350 operations. After laparotomy especially, as we all know, a woman needs absolute repose, and this can hardly be secured in a large ward where something or other is constantly going on. And the reason, I imagine, why the difference is not more marked, lies in the fact that so many hospital patients feel quite at home among, and suffer no harm from, the sights and sounds by which they are surrounded. It is fortunate for them it is so, and fortunate also for the general success of hospital work. When so much is attributed to septicity in its multifarious forms, it behoves us not to lose sight of those emotional psychical elements which are, in their way, equally important in the attainment of surgical success. We all know, too, that a prolonged operation, even if intended to impress on students attention to minute details, or a too rapid and ill-finished one, may mean subsequent excessive shock, which is one of those submerged surgical sandbanks which usually have no lighthouse placed there to warn us. *Festina lente* is not a bad motto for the operating gynæcologist.

Now one word concerning our Society's work. Free discussion tends, above all things, to elicit scientific

---

(*a*) "Churchill, "Diseases of Women," 1856.

truth and to promote our best interests. Let us encourage it by all means, so that—

> "We may hold converse with all forms
> Of the many-sided mind.
> And those whom passion hath not blinded,
> Subtle-thoughted, myriad-minded."
> (Tennyson.)

We must remember that life is made up largely of the multitude of small things, and although the great ones may appeal most, it is in the details of our work that we can best utilise our efforts. Nothing need be too trivial to bring forward if it elucidates some practical point, and enables us to render our methods more perfect. It often happens that some of the simplest everyday subjects elicit the most valuable contributions, and most useful discussions. After all, what we desire to attain is the utmost perfection in our scientific work. If everyone will take his or her part, however small and insignificant it may seem, it will be of great value in the aggregate, and make our Society what we all desire it to be—a brilliant success.

FOUR CASES OF MEMBRANOUS DYSMENORRHŒA WITH CASTS. (a)

BY S. JERVOIS AARONS, M.D.EDIN., M.R.C.P.LOND.

TRUE membranous dysmenorrhœa is by no means so common as some authorities would have us believe, though it has been described more frequently than any other form; indeed, Champneys (1) gives a formidable list of references which show the amount of attention bestowed on the subject. It will, I think, be found that cases of dysmenorrhœa with the passage of a cast from the uterus are, in comparison with the number of other forms of dysmenorrhœa, rare, so I need offer no apology for showing these four specimens.

CASE 1.—Mrs. E. M., æt. 31. Married six years. Commenced to menstruate at 14 years, 30-day type, periods last six days. Always had pain, which became much worse during the past four years. She frequently passed shreds, but never a complete cast as in the present instance; this was passed at the last period on the third day. Patient was sterile, and wished to have a family, and sought advice for this as well as for the dysmenorrhœa. On examination, uterus slightly enlarged, lying in normal position. Length of cast, 4.5 cm.; width, 4 cm. Curettage advised and carried out, November, 1905.

CASE 2.—Miss L. J., æt. 15, commenced to menstruate at æt. 13, 28-day type, periods very profuse, and last eight days. The cast was passed on the second day, and she had not previously noticed any shreds or membrane. Her periods have always been painful. Has never missed a period. The mother of the patient was anxious about the child. On examination, the hymen was found intact, and, per rectum, the uterus was felt to be of normal size and anteflexed. Length of cast, 3.5 cm.; thickness, 5 cm.; width, 3 cm. I am indebted to Dr. Dauber for permission to record this case.

CASE 3.—Mrs. M. S., æt. 35. Married eleven years, four children. Commenced to menstruate at æt. 14, 28-day type, periods last from two to six days. The pain is premenstrual, with no history of previous casts or shreds. This was passed on the third day of the period. Menorrhagia. On examination, uterus enlarged and in the middle line. Patient states that the periods have only been painful since the birth of last child. Length of cast, 4 cm.; width, 2.5 cm.; thickness, .6 cm. I am indebted to Dr. James Oliver for permission to publish this case.

CASE 4.—Miss S. L., æt. 45. Commenced to menstruate at æt. 18; last period on December 5th. Cast was passed on December 11th. Passed a cast previously (last October), and also shreds at different periods. Menorrhagia. Length of cast, 7 cm.; width at top (corresponding to fundus uteri), 4.5 cm.; at middle, 2.5 cm.; thickness, .3 cm. I have to thank Dr. Heywood Smith for this cast and for his permission to publish the case.

It is generally stated that the cast of membranous dysmenorrhœa is in the nature of a sac, but that this is not always so reference to the specimens from cases 2, 3, and 4 will prove. You will notice that all three are practically solid. In cases 2 and 4 there are no openings at the angles which would correspond to the openings of the Fallopian tubes and cervical canal; instead they taper off into points. In Case 3 these openings are imperfectly seen. I have cut sections from all except the first, and in all no cavity in the true sense of the word can be found. Case 1 is much more typical of those usually described. I have split it open to show the inside of the cast.

The cast from Case 4 is unusually long, viz., 7 cm. Champneys (2) states "that they never exceed 5 cm., and that a length decidedly greater than this, unless there is evidence that the additional length is due to the extension of the membrane to the cervix or vagina, points strongly to enlargement of the uterus, and is in favour of the diagnosis of abortion." Microscopically, the specimen proves to be a typical membranous cast, and shows no sign of the products of conception.

With regard to treatment, Case 1 was curetted and is now seven month's pregnant; in the interval between the curettage and her becoming pregnant she had no recurrence of her dysmenorrhœa. Sir Halliday Croom (3) states that patients who suffer from membranous dysmenorrhœa are sterile, and this patient certainly was prior to treatment. It will be interesting to see if, after the birth of her child, she has a recurrence of membranous dysmenorrhœa, because Champneys (4) says "not even pregnancy going to full time cures it."

Microscopically they all present much the same appearance. The substance of the cast showing connective tissue with a delicate fibrous stroma with masses of round cells irregularly distributed. In one or two can be seen an aggregation of cells in an oval-shaped envelope, suggestive of broken-down glandular elements.

For the sake of comparison, I show a cast from a case of ectopic gestation, which was passed a few days prior to operation, also one of a six weeks abortion. It will be seen at once how much these differ from those casts of membranous dysmenorrhœa which I have passed round to-night.

Since writing the above, I have received another cast, which I show, from the patient described under Case 2. It exactly resembles the first one passed except that it is perhaps a little smaller.

CLINICAL RECORDS.

LARGE FIBROMYOMA OF THE UTERUS.

By JOHN H. DAUBER, M.B., B.Ch., M.R.C.P.

MRS. H., æt. 57, a multipara, had suffered from a large fibroid tumour for the last 12 or 14 years. Ten years ago, when it reached the umbilicus, she was advised that it was not a case suitable either for hysterectomy or oöphorectomy, and that at the menopause the fibroid would begin to shrink.

The patient was a small, pale, hollow-cheeked, emaciated woman, with the abdomen enormously distended with a hard tumour reaching to the diaphragm and embarrassing respiration and the action of the heart, and the pulse rate was 120-130. In walking the patient had to lean back in order to maintain her balance.

Operation, Friday, February 8th, 1907, Mr. Ogle giving gas and ether, and Dr. Mansell Moullin assisting.

The abdomen was so distended that as the patient lay on her back the sub-umbilical incision was perpendicular instead of horizontal. As soon as the peritoneal cavity was opened a gallon or more of ascitic fluid escaped. The incision was carried to within half an inch of the ensiform cartilage. On the left the tumour burrowed beneath the broad ligament, which was pushed up as far as the costal margin. Above, the transverse colon and omentum were intimately adherent to it. The adhesions could not be broken down, and had to be clamped, cut, and tied. There were extensive adhesions on the right side to the ascending colon, and below the tumour seemed intimately incorporated with the bladder by an attachment as thick as one's wrist. This was cut off the bladder, which bled freely, but the muscular coat only being laid open was stitched together again with fine silk. The uterine arteries were tied in the usual manner, the broad ligament on the left side being incised and the left portion of the tumour shelled out by stripping the peritoneum off it. The cervix uteri, which was small and high up, was then cut across and the tumour removed. It weighed about 28 lbs. Both ovaries were left. The broad ligaments and stump were sewn over in the usual manner, and the long wound sewn up in three layers with silk, the assistant and operator both sewing at the same time. A pint of saline injection was administered per rectum, and the patient put to bed. She had been previously wrapped up in cotton wool from head to foot, with the exception of the field of operation. There was practically no shock, and the patient has made up to the present a good recovery.

The operation lasted a little over an hour.

The principal object he had in showing this specimen was to demonstrate the futility of waiting for the menopause in cases of fibroid disease. He had seen many lives ruined by this advice having been followed. He himself advised the removal of all fibroids as soon as discovered, and in no single instance had he ever regretted having given such advice.

OPERATING THEATRES.

ROYAL FREE HOSPITAL.

A CASE OF BRANCHIAL CYST.—Mr. JOSEPH CUNNING operated on a patient, æt. 18. Before beginning, he pointed out that the patient had a swelling in the left anterior triangle reaching from the parotid region to the level of the upper border of the thyroid cartilage, and about the size of an orange.

The swelling was first noticed five years ago, and had gradually reached its present size, though at times it had varied, sometimes getting larger, sometimes smaller. It had never been painful or tender.

The lump was fluid in consistence and not tense, while the tissues covering it were not adherent to it. The sterno-mastoid muscle could be demonstrated to be lying superficial to the outer part of the tumour.

There were no other lumps to be felt on either side of the neck.

Mr. Cunning remarked that this swelling was undoubtedly a branchial cyst, and that the only thing which could be mistaken for it was a chronic tuberculous abscess. But the long history of five years was decidedly against the latter, while the fact that there was no trace of infiltration of the surrounding tissues, and still more that there were no enlarged glands to be felt apart from this swelling, completely put out of court the possibility of it being a tuberculous abscess.

Mr. Cunning then made an incision three inches in length along the upper part of the anterior border of the sterno-mastoid, and after dividing the platysma, came upon the wall of the cyst. The tissues were easily peeled off it, and on its outer aspect, it was found going well out under the sterno-mastoid. The spinal accessory nerve had here to be separated very carefully from the cyst wall. Then, working round to the inner side, the cyst was found to go deeply in the neck between the branches of the carotid artery, and here the descendens noni had to be peeled carefully off the tumour. Working up higher, the hypoglossal nerve and the posterior belly of the digastric muscle were in turn exposed, and under this muscle the upper part of the sac dipped. A little careful dissection here soon freed the uppermost limit, which was running to the neighbourhood of the tonsil, and the cyst was removed whole.

Bleeding vessels were tied, and the cut edges of the platysma sutured; the skin wound was then closed. Mr. Cunning remarked that there were two very important points to be considered in connection with a branchial cyst. The first was that it should never be mistaken for an abscess and merely drained. It was easy enough sometimes to mistake the fluid contained in these cysts for pus, for it varied in character from clear serous to thicker yellow fluid, and finally to whitish stuff of the consistence of porridge. The nature of the fluid depended upon whether the lining was skin or mucous membrane. If the mistake were made of merely opening a branchial cyst, it would be found that a constantly or intermittently leaking fistula remained.

The other point of importance was that no one should operate upon these cases unless he was prepared to make a deep dissection of the neck, going between the branches of the carotid down to the wall of the pharynx, and following the cyst up under the digastric, for if any portion should be left, the cyst would soon reform.

These cysts were interesting morphologically, and were of the nature of sequestration dermoids, *i.e.*, a portion of a branchial cleft remained unobliterated, and as time went on the glands in the epithelial wall secreted and so dilated the space more and more till at last quite a big cyst resulted.

A curious feature in the last three cases of this kind he had operated upon was that they gave a history of alternating increase and diminution in size. That, he supposed, was due either to some excess in secretion or to inflammatory exudation. In the latter case it was easy to understand that traumatic causes might play a part, as these patients were usually young, and therefore subject to rougher usage than older people.

The situation of the cyst he had just removed was that of the most common type, and there was no doubt it belonged to the second branchial cleft.

Mr. Cunning called attention to the fact that he had stitched together the cut edges of the platysma. That was a precaution often neglected, but was important from the point of view of obtaining an unnoticeable scar. He had adopted that method since he first watched his colleague, Mr. James Berry, carefully stitching together the infra-hyoid muscles and subcutaneous tissue in goitre operations and observed what beautiful scars resulted.

TRANSACTIONS OF SOCIETIES.

CLINICAL SOCIETY OF LONDON.

Meeting held February 22nd, 1907.

Dr. Hale White in the Chair.

Mr. Raymond Johnson and Mr. C. E. Reynolds described a case in which

A MENINGOCELE IN THE SACRAL REGION WAS SUCCESSFULLY TREATED BY OPERATION IN AN ADULT, AFTER THE SAC HAD RUPTURED SPONTANEOUSLY.

The patient was a woman, æt. 22, in whom the tumour of the back had only been noticed for about two years. The tumour was of the size of a large orange, and after spontaneous rupture of the thin skin covering its summit large quantities of cerebro-spinal fluid continued to escape. An operation was performed on the second day, and the small opening by which the sac of the meningocele communicated with the theca was treated like the neck of a hernial sac and ligatured; the rest of the sac was removed. On the sixth day after the operation cerebro-spinal fluid again began to escape from a small opening in the otherwise healed wound. For thirty-seven days the free discharge continued; a second operation was then undertaken, and a very small opening which led into the theca was closed by suture. From this date no further leakage occurred, and the wound remained soundly healed. Several months later the woman was reported to be in perfect health. A point of interest in this case was that the tumour formed by the spinal meningocele was not noticeable until adult life had been reached, although a small dimple in the skin over the coccyx had been present from birth. It was further of interest that during the period of more than a month, when cerebro-spinal fluid was constantly escaping in large quantities, the patient presented no symptoms directly attributable to the loss.

Dr. **Hale White** referred to Dr. St. Clair Thomson's celebrated case in which large quantities of cerebro-spinal fluid dripped from the nose. The patient lost three times as much fluid that way as by the kidneys, and yet was in perfect health.

Mr. W. G. **Spencer** had operated on a similar case which was leaking and suppurating at the time. There was a dermoid cyst in the wall of the meningocele, and that was probably the source of irritation that had promoted rapid growth. In the present case the amount of fluid might have been due to local sepsis, and so caused no general symptoms, because it was derived merely from a local area. He detailed two operations he had performed in infants suffering from a like condition.

Mr. C. H. **Fagge** said that with a view to the prevention of leakage he was in the habit of first suturing the dura transversely, then dissecting up elliptical flaps from the deep fascia of the erector spinae, and suturing this longitudinally over the dura.

Mr. **Raymond Johnson**, in reply to Dr. Alexander Morison, said that no changes in the pulse rate had been noted as the result of the loss of fluid. Indeed, the only change noted anywhere was relief of the headache. He disagreed from Mr. Spencer's explanation of the source of the fluid in the present case, because cultures were sterile till quite late, and then the appearance of staphylococcus albus did not coincide with any increase in the amount of fluid poured out.

Mr. C. H. **Fagge** read the notes of a case of

RESECTION OF THE JEJUNUM AND COLON FOR CARCINOMA OF THE FORMER.

The patient, a woman, æt. 33, had had attacks of abdominal pain, relieved by sickness, for three months; sickness more severe for past three weeks. A hard lump was felt in right iliac fossa. To the left of this were seen peristaltic waves in a large coil passing from left to right. The patient looked ill. Temperature 96° F., pulse 120; she was sick several times.

The abdomen was opened on the day of admission to Guy's Hospital, December 11th, 1905. A malignant mass was found in the jejunum 18 inches from the duodenum, involving the hepatic flexure. An area of the jejunum and colon was resected and closed; double lateral anastomosis of jejunum to jejunum, and ascending to transverse colon was performed with small and large Murphy's buttons; the former was passed about six weeks, latter four weeks, after operation. Microscopically the growth was a spheroidal cell carcinoma.

Dr. **Hale White** commented on the youth of the cases recorded. He shortly described a case occurring in a man of 32. Duodenal ulcer had been diagnosed, but at the operation a jejunal growth was found and short circuited. The patient died later with secondary deposits.

Mr. T. H. **Kellock** inquired whether any symptoms of stricture had appeared as the result of the use of Murphy's button. He agreed as to the difficulty of decision in the matter of the treatment of such cases, as one was practically deprived of the two-stage method of procedure.

Mr. C. H. **Fagge** said that no symptoms at all were present in January. As a general rule, he thought that the use of Murphy's button was not good surgery, but it certainly saved time in many cases.

Mr. T. H. **Kellock** read a paper on

EXCISION OF JOINTS: A NEW METHOD OF OPERATING AT THE SHOULDER.

Attention was first drawn to the fact that comparatively little change had taken place in the technique of the operation on the various joints. Comparison was made between the operation of excision as performed at the hip and shoulder; in the former the section of bone was made within the capsule, and no muscular attachments to the femur disturbed, whereas at the shoulder the humerus was divided through the surgical neck and the insertions of the important muscles into the tuberosities sacrificed as well as, in the case of a child, the most important seat of growth of the humerus. The operation now described was an endeavour to save these muscles and the epiphyseal line, whilst still preserving a movable joint; it was carried out by removing the necessary amount of bone from the scapular instead of the humeral side of the joint. The operation as performed on the dead body was comparatively easy. After opening the joint by a long anterior incision, the muscles attached to the upper end of the humerus were retracted, the coracoid process broken, but not completely separated, and turned a little downwards with the origins of the biceps and coracobrachialis muscles. The neck of the scapula was then sawn through, and the glenoid cavity completely removed, sacrificing only the long tendon of the biceps and a part of the middle head of the triceps and structures of comparatively little importance.

The patient on whom the operation had been performed was a man, æt. 41, who had sustained a dislocation of the left shoulder, complicated by fracture at the surgical neck of the humerus eleven weeks previously. The fracture had united firmly in good position, but the subcoracoid dislocation remained unreduced. At the operation the glenoid cavity and part of the neck of the scapula were removed by gouge forceps, and the head of the humerus fell back easily into the cavity. Passive movements were commenced early. The result had been very fairly satisfactory;

flexion and extension were quite good, abduction fair, but rotation of the humerus on its own axis; all these movements were improved by exercise and rubbing.

It was pointed out that should the operation be performed again for a similar pathological condition, it might be advisable to add a posterior incision to the anterior one, and so, possibly, divide the neck of the scapula from behind, and also to remove a little more bone from the neck of the scapula than was done in this case.

Mr. W. G. **SPENCER** said it was difficult to define such a laxly used term as excision. At the shoulder joint the posterior incision had been long recommended, the circumflex nerve had, of course, to be avoided.

Mr. **RAYMOND JOHNSON** asked as to the nature of the passive movements used. He suspected that sometimes too vigorous early movement defeated its object by causing more cicatricial tissue to form.

Mr. **KELLOCK**, in reply to a question by Mr. Watson, said that he sacrificed the upper part of the long head of the triceps as well as the long head of the biceps, these were less important than the muscles inserted into the upper end of the humerus, because they had other attachments. As to the passive movements, he agreed with Mr. Johnson. In the present case he had, for special reasons, begun them on the tenth day, but, as a rule, he waited later. He recognised that the operation he now proposed was rarely applicable to cases of disease such as tuberculosis, for they usually affected the humerus more than the scapula.

BRITISH GYNÆCOLOGICAL SOCIETY.

MEETING HELD FEBRUARY 14TH, 1907.

Mr. W. D. **SPANTON**, F.R.C.S., Consulting Surgeon to the North Staffordshire Infirmary, President, in the Chair.

THE PRESIDENT: Ladies and Gentlemen,—It is sad that my first official duty should be to refer to the tragic death of Dr. Thomas Savage, one of our foundation Fellows, in the earthquake in Jamaica. He was President here thirteen years ago, and many of you will remember the admirable manner in which he carried out his duties, his geniality, his professional work, which he understood so well, and his delightful personality. He was indeed a typical illustration of what a gynæcologist should be.

Dr. H. **MACNAUGHTON-JONES** moved :—"The Fellows of the British Gynæcological Society have heard with deep sorrow of the tragic death of Dr. Thomas Savage under peculiarly sad circumstances. He was a valued original Fellow of this Society, and held the office of President with much distinction, contributing in various ways to its progress for many years. The Society deplore his loss, and would convey to his relations their sincere sympathy in the bereavement they have sustained." Dr. Savage began life as an ophthalmic surgeon, was a lecturer in natural history and botany, as well as a distinguished anatomist, and after filling these various offices, he followed the line of gynæcology. Not only did he occupy the position of President of the British Gynæcological Society, but he was also President of almost every important society and public body in the Midlands. He held the position of President of the Obstetrical and Gynæcological Section of the British Medical Association when it met in Birmingham.

Dr. A. E. **GILES**: I willingly second this proposition. Nothing that we can say will lessen the feeling of loss to his family, but we hope that it will be some comfort to them to have an assurance of the high regard in which he was held by the Fellows of this Society.

Dr. **FURNEAUX JORDAN**, in supporting the resolution, said :—I can only express to you the feeling that at our hospital we have lost one of our best friends. He was known amongst us always as a most genial, kindly, and friendly man. His kindness to everybody was absolutely unbounded, his hospitality was almost unique. He never hesitated to sacrifice himself for the sake of those for whom he cared. I think one of the saddest features of his loss is that he felt he was getting younger every year. Since he lost his arm and was compelled to give up work he told me he became younger as the years went by. Only two days before he sailed I met him on the street running along like a boy of fifteen, and he remarked, "Jordan, in a few years' time I shall be younger than you are—I get younger as the years go by."

The vote of condolence was passed in silence.

SPECIMENS.

Dr. S. **JERVOIS AARONS** showed specimens of

NOTES ON FOUR CASES OF MEMBRANOUS DYSMENORRHŒA WITH CASTS.

(which will be found on page 227 of present issue.)

Mrs. **SCHARLIEB** had seen a good many cases of membranous dysmenorrhœa. In one case she would have mistaken it for an abortion if she had not noticed the orifices of the tubes. She entirely agreed that the casts which were sometimes obtained in a case of extra-uterine gestation were much coarser and stronger.

Dr. **MANSELL MOULLIN** remarked that treatment of these cases had very little result. Curetting appeared to be a quite useless procedure. In his experience nearly all such cases occurred in sterile women. He had seen a second membrane was sometimes passed within a period of four days after the first, which showed how rapidly the membrane may form.

Dr. **HEYWOOD SMITH** asked whether any transverse sections of the casts had been made in order to ascertain if there were any indication of cavities when they were first formed, and, if so, whether they had been closed by pressure. He could hardly imagine a dysmenorrhœal membrane not to be an open sac.

Dr. **GILES** said he was interested to see that some of the casts were solid. The teaching one had was that these casts were hollow. He had only seen three cases of membranous dysmenorrhœa. As casts were formed by a kind of exudation in the cavity of the uterus, it was not surprising, perhaps, that from time to time the exudation should appear entirely solid. If the uterine cavity was distended and the exudation passed to the surface of the endometrium, becoming solidified before the surfaces came together, then they would expect a cavity. It would be interesting to hear in future cases whether it was common to have solid casts in membranous dysmenorrhœa.

Dr. H. **MACNAUGHTON-JONES** expressed the opinion that the etiology of cases of membranous dysmenorrhœa was the main point in connection with them. The old idea that they were associated with pregnancy had been long ago discarded, and it was well known that the disease very frequently occurred in sterile women. Many years ago he published a case of membranous dysmenorrhœa where he treated a patient shortly before marriage by curettage and application of chromic acid. The woman married, and shortly after became pregnant, and had no return of membranous dysmenorrhœa. He did not think that any light whatever had yet been thrown on the exact etiology of membranous dysmenorrhœa. Moreover, there were cases which were sometimes mistaken for membranous dysmenorrhœa, where a certain amount of exudation was thrown out in endometritis. Independently altogether of the treatment of membranous dysmenorrhœa, their object in curetting was to get rid of the endometritis. He did not think that the treatment of membranous dysmenorrhœa was so hopeless as some appeared to think. By the application of pure carbolic acid to the uterus, he certainly had cured such cases, and he thought that arsenic given internally was also a valuable aid in treatment. He thought that curettage did good.

The **PRESIDENT** remarked that the specimens illustrated a difficult problem. One always had the idea that the passage of membranous casts in dysmenorrhœa was part of a vicious cycle, and the cases of which they had heard that night seemed to emphasize that point.

Dr. **AARONS**, in reply, remarked that in the second case of the series an unfounded suggestion of pregnancy was made. None of the smaller casts showed a cavity. One of them showed a slight opening suggesting that it was closed by pressure. The best treatment was curettage followed by the application of nitric acid.

Dr. DAUBER showed a specimen of

FIBROMA OF OVARY FIXED IN PELVIS, CAUSING COMPLETE EXTRUSION OF UTERUS.

The patient from whom the tumour was removed stated her age as 77, but looked older. The tumour was removed by the abdomen. The operation was easily borne, and the patient made a rapid recovery without an untoward symptom of any kind. The object Dr. Dauber had in view in exhibiting this specimen was to illustrate the fact that aged patients bore abdominal and other operations remarkably well. He had lately operated on some patients between 70 and 80 years of age, performing hysterectomy or other major operations, and in every case recovery was speedy and complete.

Dr. Dauber read notes of a case of "Fibromyomata of the Uterus," and showed a specimen, which will be found under "Clinical Records," on page 228).

Dr. MANSELL MOULLIN remarked that in the second case the density of the adhesions to the bowel and bladder with the presence of ascitic fluid suggested that sarcomatous changes had already taken place, but he understood that this was not so.

Dr. H. MACNAUGHTON-JONES thought that people in advanced life, unless they were suffering from some other disease, such as disease of the kidney or liver, bore operations practically as well as young people. The other day he had a letter from a lady aged 83 from whom he removed the uterus when she was 71 years of age.

Dr. FURNEAUX JORDAN said that if a fibroid, however small, gave rise to symptoms, it should be removed. The more he saw of these cases the more he came to the conclusion that myomata should be treated in the same way as ovarian cysts.

Dr. ETHEL VAUGHAN said she thought it was important to consider the situation of a fibroid. It might be subperitoneal, and cause such severe pain, and perhaps retroversion or retroflexion of the uterus, as to require removal. In some cases, however, where the tumour was large, it did not cause any symptoms at all. She thought that operations in the case of fibroids should be limited to tumours as large as a uterus of three months' pregnancy. At any rate, the patient should be given the option of an operation, because it caused symptoms which seriously interfered with the patient's pleasure in life and her usefulness. One drawback in making an abdominal incision was that of a scar, especially in a young woman. It depended, she added, more on the position of the fibroid than on its actual size as to whether an operation should be performed or not

Mr. F. B. BOWREMAN JESSETT said he would have regarded the specimen as a rapidly-growing fibroid had he not been informed that it was of about 14 years' duration. He quite agreed that early operation was most desirable for all cases of fibroid. The operation of removing a fibroid from the uterus was so simple that he thought many women suffering from tumours of the kind might be saved a great deal of trouble and risk if they had them removed early.

Dr. HEYWOOD SMITH corroborated what had been said about the question of age and operations.

The PRESIDENT remarked that there was no age limit for surgical operations, and very often older people came through operations better than younger ones. There was no question about removing a fibroid so large as the specimen before them. He would be sorry indeed to have it advanced as a dictum from the Society that every small fibroid should be removed. He quite agreed that many small uterine tumours ought to be removed as possible sources of trouble. But if one was removed, how were they to insure the patient against others coming afterwards? What had struck him very much amongst better-class patients had been the number of cases where one had been tempted to suggest removal of the fibroid, and yet the patients were now perfectly well without any operation whatever, and leading useful lives in society. The removal of some of those fibroids might have resulted in the loss of very valuable lives.

Dr. DAUBER, in his reply, said he thought that every fibroid should be removed. He did not say that the uterus should in every case be removed. He would deal with small fibroids, not by removing the uterus at all, but only in cases of multiple or large fibroids he would do a hysterectomy. The mortality was now so slight in doing an operation of the kind under modern aseptic precautions, that it hardly needed to be considered.

Dr. MACNAUGHTON-JONES said he could not personally protest too strongly, and he would join in hoping that no opinion should go forth from that Society that merely because a woman had a myoma of the uterus the size of a walnut, or some myoma which was giving her practically no trouble, therefore one was justified in removing the tumour. The greatest and most skilled operators in the world did not operate unless some symptom arose which justified an operation. He had always advocated hysterectomy under justifiable circumstances.

The PRESIDENT then gave his introductory address (which will be found on page 225).

Mr. F. B. JESSETT, in presenting a vote of thanks to the President, said he thought they would agree with him that the address to which they had just listened was one of the most interesting addresses that had ever emanated from the Society

Mrs. SCHARLIEB, in seconding the vote of thanks, referred to the complimentary way in which the President had mentioned the services rendered to obstetrics and gynæcology by women as representing one branch of their great profession.

The PRESIDENT gracefully responded to the vote of thanks.

ROYAL ACADEMY OF MEDICINE IN IRELAND.

SECTION OF OBSTETRICS.

MEETING HELD FRIDAY, FEBRUARY 1ST, 1907.

The President, Dr. R. D. PUREFOY, in the Chair.

DR. THOMAS NEIL exhibited a chart showing a convenient methods of keeping a record of obstetrical cases.

Dr. HASTINGS TWEEDY, Sir A. V. MACAN and the PRESIDENT referred to the importance and value of being able to refer to previous records in obstetrical cases.

Dr. HENRY JELLETT exhibited apparatus for sterilising ureteral or other forms of gum-elastic catheters by means of formaline vapour. The exhibit consisted of two instruments—one of which had been brought from Germany by Dr. Gunn, who thought that it had been originally devised by a Japanese; the other Dr. Jellett had made for himself from particulars given by Dr. Gunn. Sterilisation was effected by the constant passage of coal gas, impregnated with formaline vapour through the catheter, which gas was subsequently burnt off in the Bunsen burner, which supplied the necessary heat for generating the formaline. A series of experiments were undertaken by Dr. Rowlette to determine the efficacy of the steriliser, and he reported as follows:—"I have tested the steriliser with cultures of the following organisms—(1) *B. coli communis*, the most common bladder infection; (2) *Staphylococcus aureus*, another common infection; (3) *B. anthracis*, an organism extremely resistent to disinfectants. Experiments were in each case conducted as follows:—An active fluid culture of a couple of days' standing was employed. In this culture an elastic catheter was allowed to stand for ten minutes. The catheter was then placed in the sterilisers for half an hour. It was then dipped and rinsed in melted agar, which was immediately poured out into a Petri dish and incubated at blood heat. In no case did any colonies appear. Controls were employed to establish the vitality of the cultures. The method of sterilsation seems very thorough and satisfactory."

Dr. **Hastings Tweedy** recalled that when the disinfecting properties of formaline were first discussed opinion was strongly against it when vaporised from the solid. If the dry formaline had no sterilising power it must be the coal gas in the apparatus exhibited which acted as the disinfectant.

Sir A. V. **Macan** said that anything that made a catheter quite safe after using in an infected case was a most important matter.

Dr. **Kirkpatrick** said that in experiments on the subject of room disinfection formaline was found to have slight penetrating power. Bacteria could be killed close to the opening of culture tubes, but quite a short way down the disinfection ceased abruptly at a definite line. It was not likely, therefore, to penetrate effectively into the catheters for any considerable distance. Dr. Rowlette's experiments were to a certain extent vitiated by the fact that he probably carried formaline on the catheter into the agar solution, and this formaline naturally prevented growth.

Dr. **Donnelly** drew attention to the possible action of ordinary coal gas on metallic instruments, and suggested that experiments be made to find out whether they would be injured nor not.

Dr. **Jellett** in reply said he was not disposed to take the view that formaline in the dry state would not cause sterilisation. The larger apparatus would take in a cystoscope, but he had not tried it on metallic instruments. The same objection would, however, stand in regard to them as to the use of the apparatus in disinfecting dressings and sponges—viz., that there would be a certain amount of deposit of formaline left on them which would leave sponges and the like in a too irritating state. This objection did not apply to catheters, as they could be washed in sterilised water and the formaline thus removed. He quite appreciated Dr. Kirkpatrick's objection, but did not see how it was to be overcome.

A CONTRIBUTION TO THE TECHNIQUE OF OPERATIONS ON THE APPENDAGES.

Dr. **Henry Jellett** read a paper on the above subject. He said the paper could be divided into two parts. The first part dealt with the methods, which he approved of, and adopted of performing salpingectomy, oöphorectomy, and salpingo-oöphorectomy, as well as plastic operations on the ovaries and tubes. After discussing various practical points connected with the performance of these operations he then suggested that the following principles might be laid down :—(1) Never tie the broad ligament with interlocking sutures or with a Staffordshire knot. The objections to both methods are that—first, they pull the top of the ligament together and so shorten it, and the contracted ligament in turn tends to drag the uterus backwards; secondly, they necessitate the use of silk, as it is difficult or impossible to include so great a mass tightly in a catgut ligature; thirdly that there is always a certain amount of risk of the slipping of ligatures so applied unless a considerable amount of tissue is left beyond them, and as this tissue is deprived of blood, and possibly bacteria-laden, it may subsequently slough and give rise to the formation of adhesions or even to general infection. (2) Never use silk in the presence of inflammation, as it tends to become a permanent depository of infection. (3) Never remove more of the appendages than is necessary. The retention of even a portion of the ovary adds greatly to the future comfort of the patient, and if to this is added even the stump of a patent Fallopian tube, there is present at any rate the possibility of a future pregnancy, instead of the certainty of sterility. (4) Always conclude the operation by performing ventro-suspension of the uterus, otherwise the uterus is almost certain to fall back and contract fresh adhesions, thus often causing the persistence of pain. The second part of the paper dealt with the statistics of thirty cases of adnexal disease on which the speaker had operated according to the methods and principles mentioned in the first part of the paper. It also contained a table showing the exact nature of the operations in each case, the extent of the lesion, the immediate result, and the condition of the patient when she was last seen.

Sir A. V. **Macan** said the paper opened up the whole question of operations on the appendages. The feeling on the Continent was, he said, in favour of the vaginal route as against the abdominal. The question of infection was of great importance. There were four possible infections, and the deciding of which was present was a very important question. Another question was whether it was better to remove the uterus or hang it up to the abdominal wall. The rule for choice should be—No operation if possible; next, the least operation possible, and above all, the retention of function where possible. The possibility of a woman having children in the future had an enormous effect in obviating depression of the mind; and the retention of a sufficiency of ovarian tissue to enable menstruation to continue could not be too highly praised. The feeling abroad in connection with the danger of silk as a focus of infection was that it was impossible to prevent it; hence catgut was favoured for everything except the abdominal wall and intestines. The speaker criticised the paper from the point of view of Professor Martin's latest edition, and indicated the latter's method of dealing with cases of infection and tubercular disease.

Dr. **Hastings Tweedy** said that Dr. Jellett's treatment in the cases he had cited was almost identical with his own, and they were agreed on the point of saving as much as possible. There were some points of detail, however, on which they were not in agreement, but probably they did not make much difference either way. For instance, Dr. Jellett objected to the Staffordshire knot; still it had been used successfully for many years, and he (Dr. Tweedy) considered it a quicker method of tying off the broad ligament than any of the methods suggested, and it was less liable to cause subsequent adhesions. There was not, he thought, any second opinion in regard to the use of silk in an infected case; the burying of it in the midst of septic matter must end in disaster. But it had enormous advantages in other cases. If *fine* silk was used, and was boiled in corrosive sublimate, it was capable of resisting germs for five or six days; and he had absolute proof that silk was absorbed. In regard to the question of drainage, its value lay in the causing of irritation and the exudation of serum that might possibly wash out some of the germs and do good; but drainage after twenty-four hours was seldom of any use.

Dr. **Thomas Neil** said that silk, being an animal substance, should be absorbable, but it was necessary that it should be unmixed with vegetable fibre.

The **President** said he was fully in accord with the value of preserving as much of the organs as they could where there was the least possibility of function continuing afterwards. He had been accustomed to tying the broad ligaments *en masse*, and he shared the view that, however more artistic Dr. Jellett's method might be, he was not sure that it had any great advantage over the other. He had no doubt that silk was absorbable. In operations for the removal of the appendages, where a large extent of raw surface was left on the face of the rectum, he had been content to allow the uterus to fall back, hoping thereby to prevent contact with intestines; and he thought that in some cases that was better than lifting the uterus above the appendages and leaving a raw surface as a possible source of subsequent adhesions.

Dr. **Jellett**, in reply, said he knew there was a tendency in favour of the vaginal route, and he brought forward his cases as going a certain way to show that there were no bad results attributable to the abdominal operation. The predominant feature of his series of cases was not so much the accumulation of large quantities of pus in the tubes and ovaries as extensive intestinal adhesions. That being so, he could not have got as good after-results by the vaginal route, nor could he have left the genital organs in as satisfactory a condition as appeared on subsequent examination. He had started with the view that in tubercular cases the entire pelvis should be cleared out; but in view of two of the cases he recorded he could not help thinking that removal of the diseased portions alone was sufficient. Moreover, primary ovarian infection was very rare. He thought that those speakers who advocated ligature of the broad ligament *en masse* must use silk, and there had been a general consensus of opinion that this was inadvisable.

THE SOCIETY FOR THE STUDY OF DISEASE IN CHILDREN.

MEETING HELD ON FRIDAY, FEBRUARY 15TH, 1907.

Mr. Sydney Stephenson in the Chair.

The following cases were shown and discussed.

A case of buthalmus was shown by the Chairman affecting a syphilitic infant, æt. 10 months. The condition had been observed immediately after birth. The corneæ, which had been extremely cloudy, had cleared under treatment by physostigmine and mercury internally. Moreover, the operation of anterior sclerotomy had been performed upon the left eye. The child retained fair sight.

A case of cretinism was shown by Drs. Spriggs and Higgs.

The child, æt. 2 years and 7 months, had always been backward. She was 26 inches long, circumference of head 17½ inches. She could not walk nor stand and was a typical cretin physically. The mind was about equal to that of a normal infant of 8 months. The complexion had already improved markedly since thyroid treatment was began only three weeks ago. One grain of the extract is given three times a day. The weight fell half a pound and there was considerable restlessness and fretting, which ceased when the dose of thyroid was lessened.

Dr. Leonard Guthrie always thought breast-fed children escaped myxœdematous symptoms, but had recently two cases which disproved this.

Dr. Fletcher Beach believed the result depended upon the age at which thyroid treatment began.

Dr. Poynton mentioned a case of a mother suffering from four ophthalmic goitu who nursed her child which was a cretin. This child responded well to thyroid treatment.

Dr. Porter Parkinson believed that mental improvement did not always correspond with the physical improvement by thyroid treatment.

Dr. Sutherland alluded to diarrhœa as a symptom when too large doses of thyroid were given.

A case of cerebral tumour was shown by Dr. Cantley in a boy æt. 10. For six weeks he had had attacks of headache lasting 12 hours, terminating in vomiting about once a week. For two weeks he squinted, due to paralysis of the left external rectus. He had optic neuritis and exaggerated knee-jerks, but no other abdominal signs on examination. Dr. Cantley suggested a small quiescent tuberculous focus in the superficial portion of the pores.

Dr. Hardthorne pointed out the likelihood of such cases becoming quiescent through blindness was a frequent consequence.

A case was also shown by Dr. Cantley of an infant six weeks old with a large inguinal hernia in conjunction with basal meningitis. The condition of rigidity of the abdominal muscles made it doubtful if an operation should be done at present for the cure of the very large inguinal hernia.

Mr. Mummery thought the child should be strung to a cross-bar to facilitate return of the hernia; that failing, he would operate.

Lymphangeioma or lymphatic nævus of the left side of the tongue was shown by Mr. Lockhart Mummery.

The patient was a boy, æt. 5. The surface of the tumour showed small clear walled cysts. It caused no inconvenience. Three cases of aortic regurgitation were shown by Dr. J. Porter Parkinson. They were all in girls and of rheumatic origin. In one patient, æt. 9, there were crostic diastolic and mitral systolic murmurs. In case two, æt. 12, there was only an aortic regurgitant murmur with enlargement of the left ventricle, water-hammer pulse and well marked extensive visible arterial pulsation and capillary pulse. In case three, æt. 14, similar signs were present, but in addition there was a presystolic thrill at the apex of the heart and presystolic and systolic murmurs in the same situation, the pulse was of moderate size, indicating there could be little, if any, mitral stenosis.

Dr. Spriggs considered there was no mitral stenosis. One of the cases showed the delay between the venticular contraction and the pulse due to the elasticity of the arteries.

A case of cerebral abscess after operation was shown by Mr. P. Turner. The patient, a girl, æt. 7, was operated on for an acute mastoid abscess following disease of the right middle ear on December 4th, 1906. Attacks of petitmal had been observed for a year. After operation drowsiness supervened and a left-sided convulsion occurred followed by hemiparesis. There was no headache, vomiting or optic neuritis. Granulations were found blocking the opening from the antrum into the tympanum and removed, but the dura mater was found healthy; the drowsiness and headache disappeared; ten days later headache and drowsiness came on, and a needle inserted into the tempero-sphencidal lobe showed pus, the abscess was drained and recovery was then uneventful.

A girl, æt. 3 years, with undue mobility of the knee joint was shown by Dr. Poynton. If semiflexed she could voluntarily move the tibia outwards and slightly forwards over the femur and back again into position. This movement was apparently due to the popliteus muscle. There was considerable laxity of the lateral terminal ligaments. The movement was accompanied by a clicking sound. When the limb was extended there was no lateral movement and walking was not interfered with. The articulations of the wrist and fingers were to a lesser degree more mobile than natural.

A case of "Punch"-like intonation in a syphilitic infant was shown by Dr. G. H. Sutherland. The child, æt. 3, had been blind since birth from post neuritic atrophy and general choroidal atrophy. He could not sit nor stand and was small and flabby and markedly ricketty. There was syphilitic scarring round the mouth. The speech was unintelligible and squealing or "Punch"-like. The larynx appeared normal. The exhibitor had seen a similar case in a hydrocephalic infant.

A case of infantilism was shown by Dr. L. A. Clutterbuck. The patient was a girl, æt. 13¾. Height 3 feet 4½ inches. Weight 2 stones 6¾ lbs. She was intelligent, but did not know her letters. She was only at school for a year up to about eight years of age. Breasts quite undeveloped. No history of syphilis or consanguinity in the parents. Dr. Fletcher Beach said these cases were rare in this country, but Dr. Bourneville, of Paris, had described several cases and showed that the children did grow to a certain extent, but not very much.

CORRESPONDENCE.

FROM OUR SPECIAL CORRESPONDENTS ABROAD.

FRANCE.

Paris, Feb. 24th, 1907.

Treatment of Typhoid Fever.

The mortality of typhoid fever, says Professor Robin, has considerably diminished It has fallen to 8 or 9 per cent. in the civilian population, and to 5 per cent. in the army, where the treatment is begun at the outset.

Three great facts predominate the therapeutical indications: organic destruction is increased, oxidation is diminished, and the waste of nutrition is retained in the organism. The causes which produce this retention are that of diminished vitality of the cells, insolubility of the nutritive waste, and an inferiority in the functional capacity of the emunctories.

The tissues are encumbered with this organic waste, which exceeds by 25 or 30 per cent. the quantity contained in the healthy tissues. The period known as the crisis is accompanied by a larger elimination of the waste, and precedes by 24 or 48 hours the improvement in the condition of the patient.

The first indication in the treatment is to diminish the organic disintegration. The patient must be nourished, but by milk and beef tea only. A quart and a half of milk and one quart of beef tea are sufficient. Coffee, champagne, or wine in small quantities, and largely diluted, are useful in aiding oxidation and the elimination of the waste of nutrition.

As to medicine, small doses of quinine (6 grains of hydrochlorate morning and evening) can be prescribed. Cinchona extract may replace the quinine.

Ext. of cinchona, dr. 2.
Benzoate of soda, dr. 1.
Rum, oz. 2.
Syrup of gum, oz. 3.
Water, oz. 5.

A tablespoonful every two hours.

Antipyrine should not be given, as it diminishes the oxidation and reduces the quantity of urine. However, at the outset of the malady one dose (6 grs.) of pyramidon might be given, and rarely repeated, as it has a depressing action on the patient. Cold bathing should be prescribed where the temperature exceeds 102 degrees. The first bath might be given relatively warm, so as not to produce too great a shock to the patient. It might be given at 89 degrees, and lowered gradually to 77, 71, or 68 degrees. Ten minutes in the bath will be sufficient at first, and as the patient gets accustomed to it, 15 minutes. The bath will be renewed night and day every three hours as long as the rectal temperature shows 102 degrees. Ten minutes after each bath the temperature should be taken, and the fall invoiced. While the patient is in the bath he may be given a little champagne, while his shoulders and legs should be rubbed, but care should be taken not to touch the abdomen. A jug of water 6 or 8 degrees colder than the bath should be poured on his head, or in the case of a woman a cold compress.

The only counter indications to cold bathing are intestinal hæmorrhage and cardiac weakness.

To encourage elimination of tissue waste, the energy of the circulation should be maintained; hence the utility of dry cupping, which diminishes the cardiac labour by relieving the congestion of the lungs and favouring the absorption of oxygen. The heart should be strengthened by sparteine, digitalis, and especially by cinchona and alcoholic drinks. Elimination by the intestines is assured by the employment of enemas. If all these precautions are taken, it is rare, says Prof. Robin, that the patient does not get well.

As to dietetic regime in the period of convalescence from typhoid fever, it should be prescribed with intelligence and caution. No solids should be allowed for a week after the temperature has become normal, and until all trace of albumen has disappeared, and here the density of the urine is of primary importance to guide the attendant. If the density is found to be 10.18, for instance, the two last figures (18) will be multiplied by the invariable number 2.33; the result is 41.94. If this figure exceeds 50, the consumption of solids must be retarded, in spite of the entreaties of the patient. But in every case the patient will be led very gradually to usual diet.

Certain complications may have to be treated in the course of typhoid fever, amongst which may be mentioned vomiting, pulmonary congestion, tonsillitis, perforation, and intestinal hæmorrhage.

The vomiting may be treated with Vichy water and a small blister over the epigastrium. The blister is left on seven hours, and replaced by a linseed poultice for an hour, when the raised blister is cut and 2 grains of powdered opium inserted under the skin. This is an active remedy, and without danger. Inhalations of oxygen gas arrest also the vomiting, and may be ordered.

The pulmonary congestion is best treated by the cold baths, dry or wet cupping, and alcoholic mixtures.

For tonsillitis the following gargle:—

Naphthol, gr. 4.
Perborate of soda, dr. 4.
Peppermint water, 1 quart.

Perforation requires laparotomy, and many successful operations have been recorded. After perforation, hæmorrhage is the most dreaded complication.

Here the enemas must be stopped as well as the cold bathing. Iced milk in small quantities, complete rest, and every hour alternatively a tablespoonful of each of the following mixtures:—

Ergoline, dr. 1.
Gallic acid, gr. 10.
Syrup of turpentine, oz. 1.
Water, oz. 4.

Chloride of calcium, dr. 1.
Syrup of opium, oz. 1.
Water, oz. 4.

GERMANY.

Berlin, Feb. 24th, 1907.

INFECTIOUS DISEASE IN BERLIN.

In December, 1906, 606 deaths took place in Berlin from infectious diseases. There were 13 deaths from measles, 21 from scarlatina, 35 from diphtheria and croup, 22 from whooping cough, 55 from influenza, 12 from puerperal fever, 315 from pulmonary and laryngeal phthisis, 51 from tuberculosis of other organs. Other causes named are cancer 190 deaths, diseases of the heart 295, inflammation of the lungs 231, intestinal catarrh 90 and amongst these 85 of children under 1 year of age; 7 from vomiting and diarrhœa, 6 of them under one year of age. The number of deaths of children under 1 year of age was 639=22.71 per cent. As a set off against this mortality it may be noticed that typhoid and typhus fevers as causes of death are conspicuous by their complete absence.

There were 3,310 patients in the city hospital at the end of the month, the total accommodation at these places being 3,966 beds. There were 121 female patients in the institution for sexual diseases. In the various lunatic asylums and institutions for epileptics there were on January 1st, 1907, 4,919 inmates and 2,641 persons were under private care.

Complaint was made of the inadequacy of the provision for convalescents and it is claimed that if there were further accommodation in this direction patients need not be detained so long in hospital. For various reasons they may be unfit to be sent home, whilst on the other hand they are no longer in need of hospital treatment. If each hospital had its own convalescent home much would be gained, particularly on the part of the patients themselves.

It is announced that the Deutsche Gesellschaft for the Combating of Sexual Diseases will be held at Mannheim on May 24th and 25th. A special discussion will take place on Sexual "Pädagogik," this will include the duty of the mother, the home, the common school, instruction on sexual matters in higher schools for those about to leave school, seminarists, continuation schools in the country, literature for youth and sexual dietetics.

At the Medical Society, Hr. H. Neumann introduced the subject of the

NATURAL FEEDING OF INFANTS IN PRACTICE.

He pointed out how the practice, especially in the better class families, had fallen off. From statistics it appeared that the number of unsuckled infants had increased by two-thirds between the years 1885 and 1900, and he asked the question whether scientific knowledge of the artificial feeding of infants had advanced so far that we as physicians could quietly look on. It was true that the generalisation of the Soxhlet principle of preparation of food had been of great service, and especially since the overheating of milk had been given up, and the view had become more widespread of the great importance of the good and unobjectionable milk supply. The consequence of this was that the acute intestinal disease of infants scarcely occurred at all now in families who were well off, but they were still very frequent amongst those without means. But as regarded the chronic intestinal nutritional disturbances the infants of well-to-do families were not so much better off, as the advances made in the feeding of infants were not the common property of the general profession. The idea still seemed to prevail that the more food the infant took the better; they very often had to try different kinds before hitting upon the right one for the case, which when once found they were so enamoured of it that they ordered it for every one without distinction. But in artificial feeding we always ran a great risk, and the younger the infant the greater this was. It was true that we often did well enough when the infants were not of low class physically, *i.e.*, when they were not premature or twins. In particular one must not be deceived by rapid increase of weight; for instance, one may find great increase of weight, but convulsions are apt to occur. Great increase was often followed by rapid loss from intestinal disturbance and moreover rickets was liable to come on with its associated convulsions and spasms of various kinds. Rickets did not come on if the food was proper. The disease depended principally on heredity; it showed itself by certain signs in the new-born, particularly in the skull. This must be borne in mind in the feeding of infants. The physician must examine the other members of the family as to signs of former disease and on any signs of heredity showing he must insist on the natural feeding of the child. The time of the birth was also of importance as regarded rickets. If the birth was in August or September we often saw rickets develop later on with artificial feeding from insufficiency of fresh air as the infant was kept more in the house; it was the same with the tetanoid irritability. Rich and poor were affected alike in regard to this. Congenital rickets was often arrested by breast milk, but if nothing were done until the rachetic symptoms were developed, it was difficult to get the child to take the breast. Breast children were as a rule not so fat as artificially fed ones, but they were more muscular and lively. Then for a time we saw Barlow's disease amongst infants from over-heating of the milk; since the cause became known the disease had disappeared.

The decline in suckling, both in the well-to-do and among the poor, was not due to either social or physical causes, but solely to fashion. In well-to-do families less than 30 per cent. of the infants were breast-fed. When the milk came early and freely suckling came easier. But when it did not come so, but with pain, the mother made up her mind to it less readily and the attendant did not press for it enough, often out of regard to the mother herself. The fault of not suckling often lay with the doctor.

Grave chronic diseases, especially phthisis, were objections to suckling, but according to recent observations, especially those of Schlossmann, the milder form was not harmful either for mother or child. Again, suckling was often refrained from as it caused too much exhaustion for the mother, but really it only very rarely had such an effect. If the mother was weakly, anæmic and nervous from suckling, things could generally be put right with proper treatment. Public opinion had to be acted upon and this duty of enlightening the public, which fell on the physician, should not be neglected.

On putting the infant to the breast the mistake was often made of thinking that it should have food at once, and that if there was not enough milk artificially prepared food must be given. This was a mistake, for it took time for the milk to come after the birth of the child, and during the first few hours the infant required no food. With very weakly children a little Soxhlet milk might be given to make it strong to suck. A wet nurse with her child might also be procured and the nurse's child put to the breast to help bring the milk. The infant must not be put to at stated hours, but only when it shows signs of wanting something. Otherwise digestive disturbances might easily be set up by overfeeding.

AUSTRIA.

Vienna, Feb. 24th, 1907.

OSTITIS FIBROSA.

HABERER presented a boy, æt. 13, to the "Gesellschaft der Aerzte," with the skeleton bent and tumefied. The Röntgen rays showed the bony tumours to be large cysts in the bones. Excisions for microscopical examinations proved the growths to be largely composed of giant cells with a fibrous transition of the marrow which had transformed the bony substance and medulla into sarcomatous tumours with narrow isthmi between, and forming a kind of multiple giant cell sarcoma of a benignant character, as the disease, according to history, had existed for ten years, having commenced when the boy was three years of age.

DYSENTERIC TOXIN.

Doerr gave a short history of dysentery in the army, and the various theories in literature. He next recounted his experiments with guinea-pigs and the toxin obtained from the dysenteric with anatomical and histological specimens to show the changes were those caused by the Shiga-Kruse bacilli, which he cultivated and injected as an antitoxin with marked success. He also showed the effects of Paltauf's experiments in the Sero-therapeutic Institute of Vienna, which justified his own belief in a powerful antitoxin.

RONTGEN APPARATUS.

Stein showed the members a novel construction of this instrument to take radiographs, ortho-diagraphs, ortho-photographs, and to act as a radioscope in the lying, sitting and standing postures. This, he contends, will be of immense advantage on the field of battle or open air, where all luxuries are absent.

Freund thought the instrument was an excellent universal one, but was afraid that its very portability was a blemish in its stability which would seriously affect the ortho-diagraphs. The centering of the tubes would be another grave matter for correction in such a light instrument. Otherwise the idea was a good one. Stein's method obviated the tedious operation of exchanging tubes or producing a clearer light when desirous of taking an orthograph with the radioscope Stein admitted these defects, but thought they were compensated for by the information afforded the economy in case of injury in transit and the changes of temperature.

Ranzi thought there were a number of similar instruments put on the market during the year, all claiming superiority.

LEPROSY.

Deyke and Bey, from Constantinople, have prepared a bacterial fat which they affirm is a protective, but not a cure, for leprosy. This substance is obtained from the cultivation of the streptothrix leproides, which forms a thick gluey fluid, and from this property has been named "Nastin," which is injected into patients where the disease is moderate or mild, when the morbid process seems to receive a check and recede in many cases. In several cases the disease disappeared entirely, and no trace of the morbid products could be found. Severe cases were very little affected, and no beneficial effects could be observed. The explanation offered is that the true bacillus or genuine parasite is not exactly known, although the "Nastin" may be similar as a biological product, though not the exact counterpart, of the exciting changes. They consider the "Nastin" injection, however, an active immunising agent, and therefore a preventive, but not a curative product. "Nastin" seems to be a glycerine ester of the tubercular bacillus, and therefore a biological fat.

FROM OUR SPECIAL CORRESPONDENTS AT HOME.

SCOTLAND.

BRITISH MEDICAL ASSOCIATION.—A most successful joint meeting of the Scottish branches took place in Edinburgh on February 22nd, at which a large number of interesting cases were shown, and several demonstrations of special methods of treatment, etc., given. Much interest was taken in the museum which had been got together for the occasion, the feature of which was a large series of most beautiful and lifelike wax casts of diseases of the skin prepared by Dr. Cranston Low, who has recently been appointed dermatologist to the Infirmary. The fidelity with which these depict the conditions they are intended to represent was a matter of admiring comment among all who saw them. Among a great many other exhibits. Professor Annandale's series of preparations illustrating various surgical diseases calls for mention on account of the large field it covered. Mr. Henry Wade, curator of the Museum of the College of Surgeons, showed a number of pathological specimens mounted in a novel manner which should be very convenient for teaching and demonstration purposes. Coming into the same category was Mr. Richard Muir's exhibit of a permanent method of mounting bacterial cultures as museum specimens. Demonstrations of the pathological and clinical features of cerebro-spinal meningitis were given by Drs. John Thomson, Fowler, and Stuart McDonald, by Drs. Shennan and Ritchie, and by Dr. R. W. Philip. Dr. Haig Ferguson showed a new form of obstetric bag, with steriliser attached, and an extensive series of surgical and gynæcological specimens were shown by Messrs. Brewis, Stuart, Caird, Dowden, Shulters, Miles and others. Drs. Malcolm Campbell, Gardiner, and Watson showed photographs and microscopic preparations illustrating the effect of varying diets on animals, and Dr. Nicholson exhibited a series of photographs and tracings of cases of myxœdema, eclampsia, and Graves' disease illustrating the action of the thyroid gland. The clinical meeting was well attended, and among cases shown were several of exceptional clinical interest. Drs. Ford Robertson and McRae showed two cases of general paralysis undergoing special serum treatment. Dr. J. V. Paterson showed the unusual condition of orbital aneurism following fracture of the base of the skull; Mr. C. W. Cathcart, a patient after removal of the Gasserian ganglion; Dr. Byrom Bramwell a case of hemiplegia with crossed plantar reflex; the plantar reflex on the non-paralysed side was flexor, on the left (paralysed) side extensor. On stimulation of the right sole a crossed flexor reflex—flexion of the left big toe—was obtained. Mr. Alexis Thomson showed a patient with supposed fracture dislocation of the lower cervical spine, with symptoms of complete destruction of the first dorsal segment of the cord. After an accident motion and sensation were abolished below the third rib; there was anæsthesia in both arms along the region of the ulnar nerve, paralysis of most of the small muscles of the hand, paralysis of the sympathetic, retention of urine, and priapism. He was not expected to live more than a month. At the end of three weeks improvement began, and has steadily continued, so that at the end of a year he could walk with a stick, and had only slight spasticity and abolition of sensation in the legs. Other exhibitors of cases were Dr. Farquharson, Dr. Edwin Bramwell, Dr. Norman Walker, Mr. Miles, Dr. Caverhill, Mr. Cotterill, Dr. James, Dr. Haig Ferguson, Dr. Gardiner, Mr. Stiles, Dr. Gilson, Mr. Caird, Dr. Fleming, and Mr. McGillivray. Dr. Dawson Turner gave an electrical demonstration, including the method of estimating the hæmorenal index; Mr. Miles demonstrated the ambulant treatment of fractures and ulcers of the leg; Dr. Caverhill gave a lantern demonstration of British and Continental sanatoria; and Professor Schäfer a demonstration of his method of artificial respiration. In the evening the members of the Association dined together in the North British Station Hotel.

MEDICAL OFFICERSHIP OF THE EDINBURGH SCHOOL BOARD.—On the 18th inst., Dr. John Hally Meikle, M.D., B.Sc., was appointed Medical Officer to the Edinburgh School Board at a salary of £400. Dr. Meikle is at present senior assistant and bacteriologist at the City Hospital.

CRICHTON ROYAL ASYLUM.—Dr. Rutherford, the superintendent, takes the occasion which his annual report affords of making some reply to Lord Rosebery's remarks on the enormous increase of lunacy, which excited considerable interest and comment at the time of their utterance some months ago. Dr. Rutherford asserts that there is no increase of insanity among the wealthier classes—*i.e.*, those who pay £60 per annum and upwards as patients in asylums. The same may be said of the well-to-do artisan classes. From a return made by the clergy of Dumfries and Galloway in 1831 there was then in the counties 333 insane persons. In the asylums to-day there are 325. A striking feature is that, of the 333 seventy-four years ago, only 143 claimed parochial relief, while 190 did not claim charity. The great increase in the population of our asylums is entirely from the lowest class of society, a class which is increasing in all our large towns. It is a class which displays little mental activity, lives under insanitary conditions, abuses stimulants, and is exposed to exhausting labour and contagious disease. The tendency of those whose brains are abnormally constituted is to sink step by step, through the various grades of society, until they reach the final sedimentary deposit of pauper lunacy. In London the increase of asylum inmates has been very fast, and it is the same in all large towns. The chief increase in the pauper lunacy of Dr. Rutherford's district has been from the urban districts—from the rural parishes the numbers are even less than they appear in the return of 1831. A great impetus was given to pauper lunacy by the giving of the 4s. grant in aid of local taxation in 1875. From that time a change took place in our asylum inmates. Persons who are weak-minded and senile, or otherwise troublesome, many of whom used to be accommodated in poor-houses, are now sent to asylums. To a large extent the alleged great increase in lunacy is therefore due to—(1) an extension of the area of pauper lunacy; (2) to the accumulation in asylums of persons for whose detention there is no urgent necessity, and who do not materially benefit by asylum treatment; (3) to the artificial stimulus given by modern legislation to that accumulation. As regards Lord Rosebery's objection to the expenditure on the insane, Dr. Rutherford urges the desire among civilised communities to do all that can be done to alleviate suffering. Far from being "tombs of the intellectually dead," asylums are largely curative. It is a comfort to think that no curable person can enter an asylum and not be cured. As it is, even with the drawback that more than half the cases are incurable on admission, statistics show a recovery rate of 40 per cent. The Scottish asylums are far from being tombs. Good work is being done in them as regards the recovery and care of the patients, and in the laboratory of the Scottish asylums as regards investigation into the causes of insanity and the best means for its prevention.

BELFAST.

THE HEALTH OF BELFAST.—It will be remembered that last autumn at the time of the appointment of a new Medical Officer of Health for the city, an effort was made to obtain a Royal Commission to inquire into the unsatisfactory health of the city. It was said to be owing to difficulties with the Treasury that the Commission was not granted, but the matter was not allowed to drop, and it has now been announced that we are to have a Commission of Inquiry, appointed by the Local Government Board. The members are: Colonel Harding, of Leeds (Chairman); Dr. Chalmers (Medical Officer of Health for Glasgow); Dr. Mair (Medical Inspector, Local Government Board, England); and Mr. P. C. Cowan and Surgeon-Colonel Flinn (of the Irish Local Government Board). The reference is an exceedingly wide one, and will bring every question connected with the health of the city into the scope of the inquiry.

THE WATER SUPPLY AND TYPHOID.—Following on the reported discovery of the typhoid bacillus in the Belfast water, as noted in this column last week, a searching inquiry is now in progress, three experts having been brought over by the Water Commissioners. These are Professor Percy Frankland, of Birmingham; Dr. A. C. Houston, Bacteriologist to the Metropolitan Water Board, London; and Dr. Mervyn Gordon, of St. Bartholomew's Hospital. For years past the Belfast Corporation has blamed the water supply for our constant epidemics of typhoid, and the Water Commissioners, in reply, have asked for evidence of contamination, and have blamed the general sanitary conditions of the city. Now at last we may hope to have an authoritative pronouncement on the subject.

CEREBRO-SPINAL MENINGITIS.—There have now been about 110 cases of this infection in Belfast, with about 58 deaths, and there are still 36 cases under treatment at the Purdysburn Fever Hospital. The serum treatment is being tested, but the medical men in charge refuse to express any opinion as yet on its efficacy.

LETTERS TO THE EDITOR.

LAW FOR LAWYERS AND LAW FOR DOCTORS.

To the Editor of THE MEDICAL PRESS AND CIRCULAR.

SIR;—You will do a service to the profession if you will continue to keep to the front a record of the anomalous condition of the law. The profession are not by any means fully informed on the subject, whilst the people of all classes are almost entirely ignorant. Everyone must agree with you that if the story were once made fully public a demand for reform would arise outside as well as inside the profession. The case to which I would now draw attention occurred at a London Police Court last week. A man who had been struck off the Rolls was fined £10 and £5 costs for using the title of solicitor. There are a large number of medical men whose names have been removed from the register for infamous conduct who still go on practising and using titles, sometimes with a prefix before the letters, as ex-M.D.Edin., etc. In some cases these men have become advertising quacks of a low fraudulent type, and yet in the present state of the law no attempt can be made to interfere with them either by medical authorities or the police.

I am, sir, yours truly,
AN OBSCURE PRACTITIONER.

OBITUARY.

JOHN BOURNE, M.R.C.S., L.S.A., OF WEARDALE.

DR. JOHN BOURNE, of St. John's Chapel, has just passed away at the ripe age of 85. He qualified as a member of the Royal College of Surgeons as far back as 1844. For over sixty years he was a medical man, resident in Weardale, and for nearly half a century acted as medical officer to the Weardale Board of Guardians. As a matter of fact, he was the first medical officer ever appointed, and his salary was £28 per annum. He was much esteemed locally, not only for his skill as a surgeon, but for his many social excellencies. His personality is an interesting link with the past, inasmuch as he was nominally associated with the prototype of Mr. Wackford Squeers, of Dotheboys Hall, immortal sed in "Nicholas Nickleby." He went to London University College with a son of the reputed Squeers. In relating his remembrances, Dr. Bourne never failed to emphasise that in his opinion Dickens's story, so far as Dotheboys Hall was concerned, was exaggerated, and would not admit that exceptionally cruel treatment was ever meted out to the pupils of that now noted academy.

FRANCIS RICHARD CARTER, M.R.C.S., L.S.A.; OF CHAPEL-ALLERTON, LEEDS.

WE regret to announce the death of Mr. Francis Richard Carter, of Chapel-Allerton, which took place suddenly at his residence on the 21st inst. He was the son of the late Dr. J. B. Carter, who was in practice at Chapel-Allerton for nearly fifty years, and his grandfather and great-grandfather were also medical men. He received his professional training at the Leeds Medical School. He qualified as a surgeon at the age of 21, joined his father in partnership, and had been in practice for the last thirty-five years. His elder son, following the professional tradition, is a student of medicine at the University of Leeds.

SIR WILLIAM HINGSTON, OF MONTREAL.

WE regret to announce the death of Sir William Hingston, one of Canada's greatest surgeons, on the 19th inst., at Montreal, aged 78. Sir William, who was the son of the late Lieutenant-Colonel S. J. Hingston, was born in Quebec, and after graduating at McGill University he visited Europe, and obtained diplomas in Scotland, France, Prussia, Austria, and Bavaria. Upon his return to Canada he began practice in Montreal, which henceforth became his home. He was the first secretary and afterwards president of the Canadian Medical Association; he organized the first Board of Health in the Dominion, and when Bishop's College Medical School was founded he became professor of surgery and afterwards dean of the faculty. In 1895, he was knighted for his distinguished services to medical science, and in the following year was called to the Senate by Lord Aberdeen. Sir William Hingston married in 1875 Margaret Josephine, daughter of the late Hon. D. A. Macdonald, formerly Lieutenant-Governor of Ontario.

SURGEON-MAJOR WILLIAM CAMPBELL SEAMAN, R.A.M.C.

SURGEON-MAJOR SEAMAN, who died on February 14th at North Kensington after a long illness, at the age of 88, received his first appointment as assistant surgeon in 1841, and was promoted surgeon in 1851. He served with the 72nd Highlanders in the Crimea, and was present with the expedition to Kertch and at the siege and fall of Sevastopol, including the attack on June 18th. He also served through the Sepoy revolt, and was present at the siege and fall of Kotah and the subsequent campaign in Central India. He retired in 1866 with the honorary rank of deputy-inspector-general.

DR. WRIGHT, OF BOTTESFORD.

WE regret to announce that Dr. James Wright, of Bottesford, died last week from bronchitis. The deceased was in his 85th year, and was for many years a notable figure in Bottesford and district. His grandfather was a medical practitioner in the place a century ago, and his father practised as a surgeon at East Bridgford. Dr. Wright himself came to Bottesford more than half a century ago, and established a medical practice. A few years ago Dr. and Mrs. Wright received the congratulations of a wide circle of relatives and friends on the occasion of their golden wedding. Dr. Wright suffered a great blow by the death of his youngest son, Dr. Frank M. Wright, who was killed at Bottesford railway station in August, 1895.

AT a meeting of the Harveian Society of London on Thursday, March 7th, Mr. Watson Cheyne, F.R.S., F.R.C.S., will open a discussion on the Diagnosis and Treatment of Fractures in the neighbourhood of a Joint, and will illustrate his remarks with skiagrams. The following have promised to speak:—Prof. Howard Marsh, Mr. Edmund Owen, Mr. Pearce Gould, Mr. Arbuthnot Lane, Mr. Robert Jones, of Liverpool, Mr. Lynn Thomas, of Cardiff. Members of the medical profession are invited to attend.

SPECIAL ARTICLE

UNIVERSITY EDUCATION IN IRELAND.

WITHOUT doubt the most important event within the past week in regard to the University question has been the meeting of the Senate of the Royal University of Ireland. It will be remembered that shortly before the late Commission met the Senate passed unanimously the following resolution :—" That in the judgment of the Senate of the Royal University it would be disastrous to the interests of education in Ireland, and gravely injurious to the welfare of the country, to concentrate the control of higher education in one University."

Now, however, its attitude has changed and at a special meeting held on Wednesday the following resolutions were proposed by Sir Christopher Nixon, M.D., Vice-Chancellor of the University and seconded by the Rev. Dr. Hamilton, President of Queen's College, Belfast :—

(1) " That while the Senate feels that it was its right and duty, as long as the various plans for the settlement of the question of University Education in Ireland were under consideration, to express its views clearly and strongly on the undesirability of establishing a single rigid system of University Education, shaping the whole intellectual culture of the country in one mould, now that the outlines of a scheme have been put forward in the name of the Government, with whom the responsibility rests, the Senate does not deem it proper to take any course which might prevent or obstruct the immediate removal of one of the greatest and most crying grievances under which the Irish people labour. The Senate by its own action in asking for a Royal Commission had already shown how keenly alive it was to the urgent need of having this question dealt with ; and they therefore cordially welcomed the announcement that the Government will take it in hand during the present session of Parliament.

(2) " That whilst the Senate is prepared to give the most careful and friendly consideration to the scheme of the Government when published in full detail, it submits the expression of its conviction that in any scheme which would involve the establishment of one or more federal universities, it is essential in order to avoid the evils of one stereotyped system of higher education that there should be granted to the federal colleges the largest possible amounts of autonomy on the lines recommended unanimously by the Robertson Commission, and with practical unanimity by the recent Commission."

A further resolution was proposed by Dr. Leslie and seconded by Dr. Windle, as follows :—" That the following statement be adopted :—' That, in justice to this University, the Senate feels it a duty to enter a protest against certain statements regarding it which Mr. Bryce is reported to have made in his speech on January 25th.'

" The Senate believe that if he had been correctly informed of the actual working of the University and if he had borne in mind the limitations imposed on it by its Constitution, Mr. Bryce could not have said, as he is reported that ' the Royal University has not been so far a success,' that ' it has in no sense prospered,' seeing that in the twenty-five years of its existence the number of candidates presenting themselves yearly at its Examinations has been steadily growing larger, until in the last Session (1906) it reached the huge number of close upon 4,000, or nearly four times the number of students on the rolls of the University of Dublin, and that it has many of its students holding distinguished positions in all parts of the British Empire.

" Nor was it accurate to describe the Royal University as a ' mere Examining Board,' unless it be understood that the University of Dublin, which also gives its degrees to non-resident students on mere examination, may also on that account be called a mere examining Board ' ; especially bearing in mind (1) the fact that independently of the large number of students on the rolls of the Royal University, who present themselves from teaching Colleges like Maynooth, Blackrock, Clongowes, and Clonliffe, and from Women's Colleges like the Alexandra, Victoria, Loretto, and Dominican Colleges, independently of all these— the six teaching colleges, which are officially connected with the Royal University more closely in regard to some of them than any colleges at Oxford or Cambridge are connected with their respective Universities— have on their joint rolls a larger number of students receiving Collegiate instruction than can be counted on the rolls of Trinity College.

" And (2) the fact which is generally overlooked, that unlike the University of Dublin or Queen's University, which are spoken of as teaching Universities, though neither of them ever spent a pound of its income for teaching purposes, the Royal University has from the very first spent a considerable portion of its yearly income in paying the salaries of its Fellows, whom it charges expressly with the duty of teaching in one of its recognised colleges."

The first of these resolutions is a remarkably one, inasmuch as whilst the Senate " cordially welcomes the announcement that the Government will take it (the question of university education) in hand during the present Session of Parliament " it again places on record " its views clearly and strongly on the undesirability of establishing a single rigid system of University Education, shaping the whole intellectual culture of the country in one mould." Apparently, then, the Senate has decided to bless what it clearly and strongly considers to be undesirable. To the casual observer this seems rank opportunism, but of course it also may be high diplomacy.

In this connection the evidence given by the Rev. Dr. Hamilton, President of the Queen's College, Belfast, before the Commission is very interesting reading. Dr. Hamilton had been asked whether the resolution of the Senate of the Royal University (which we quote at the commencement of this article) had been passed at a large meeting of that body, and his reply was as follows :—

" Yes. And when your lordship recollects the constitution of that Senate, that we have upon it Protestants, Roman Catholics, representatives of all churches, heads of colleges, teachers in colleges, and members of all professions, clerical, medical, and legal, you have a body which, I think, speaks with exceptional authority ; and when you recollect that that Senate has been dealing with Irish higher education now for twenty-six years, and has had full experience of all the difficulties under which it has to be carried on in Ireland, I think that a very large amount of value ought to be attached to the deliverance of such a body of men.

" I should like to say, again, that Queen's College, Belfast, is entirely opposed to the solution which your lordship has mentioned to me, I thought it right before coming to give evidence here to convene a meeting of the professors, because I felt certain that their views would be of very much greater weight than mine. That meeting was held on the 2nd of this month, and the following resolution was passed unanimously :—' That the corporate body of Queen's College, Belfast, does not think it desirable that this College should be introduced into the University of Dublin, or be connected in any way with that University ; and it requests the President to lay this, its unanimous opinion, before the Royal Commission.' "

In answer to further questions he replied :—" In the next place, it is always equally unfortunate, I think, to have a forced marriage between two people who do not want to be married. Now, as far as I understand, Trinity College, Dublin, as represented by its governing body, does not want this connection with us, and the resolution I have placed before the Commission shows that Queen's College Belfast, does not want it. It would be an unhappy kind of marriage if the two were brought together against their will. . . . Really, can see no solid argument for this solution either as regards Trinity College, Dublin, or Queen's College, Belfast, and I am afraid that its adoption would be attended by serious dangers, not only to these two Colleges, but to learning and to Ireland—dangers so serious and so great that for my part I cannot view them without dred."

Dr. Anderson, President Queen's College, Galway, said :—" To unite in any way in the same University two Colleges of so different types as Trinity College, Dublin, and Queen's College, Galway, would, I submit, be profitable to neither."

Dr. B. C. A. Windle, President Queen's College, Cork, said :—" In Ireland a common University would bring together a group of Colleges differing in age, in wealth, in religion, and in ideals. What would be the result ? In my opinion such a scheme would convert the National University into a cockpit—a cockpit, too, into which all the birds would go spoiling for a fight."

Rev. Dr. Delany, J.S., President of University College, Dublin, said :—" I do not see any advantage in bringing anybody against their will into any system. As a rule, if you bring men into a system against their will, you put their backs up to go the other way, and you alienate outside feeling in the country. . . . I believe all the people would be alienated, and that they would look upon it as an act of tyranny to force them together in that way. I do not see that it would lead to their liking one another afterwards ; on the contrary, I am led to believe from recent information which I have received from several of my students in Germany, that there, far from having brought together Protestants and Catholics, there is a deeper antagonism between Protestant and Catholic students attending the same University than has ever been found in Ireland."

All these gentlemen are members of the Senate of the Royal University and were present at the meeting on Wednesday last.

A meeting of the Catholic Young Men's Association was also held during the past week. It was addressed by several influential Catholic laymen, amongst whom was Mr. McArdle, F.R.C.S.I., and it passed a resolution expressing satisfaction with the scheme proposed by the Government.

REVIEWS OF BOOKS.

MASSAGE AND ELECTRICITY (*a*).

Dr. Stretch Dowse's " Lectures on Massage and Electricity " have now attained the dignity of a sixth edition, so that we are called upon to do little beyond congratulating the author on his well-deserved success. Medical books unless they really meet and fulfil a demand do not run into edition after edition, and it may safely be concluded from the vogue of Dr. Stretch Dowse's work that it is highly esteemed. The full, painstaking account that is given not only of the physiological action of massage and electricity on the tissues, but also of the practical manipulations which are most advantageous in various conditions, enables readers who are not thoroughly *au fait* with the subject to render themselves so, and it is a mere platitude to-day to say that a knowledge of massage and passive movements is as necessary to the practitioner as a knowledge of drugs. In fact the case may be put more strongly. There seems little reason to doubt that therapeutical measures will largely supplant drug treatment in the medicine of the future, and among such therapeutical measures movements active and passive are likely to bulk largely. Much that is evanescent undoubtedly exists in hygienic fashions just as in drug fashions, but massage and electricity have come to stay, and acquaintance with their potentialities and with their limitations is an essential part of a modern practitioner's mental outfit. Such an acquaintance can be satisfactorily made through this book.

EXPERIMENTS ON ANIMALS (*a*).

We venture to hope that Mr. Stephen Paget's " Experiments on Animals " is too well known to need much description from us in this, its third, edition. Mr. Paget was for many years secretary to the Association for the Advancement of Medicine by Research, and it occurred to him that it might serve a useful purpose if he employed the knowledge he gained in that capacity by writing a popular book, showing what experimental research really had done for medicine. The anti-vivisectionists for years had being going up and down the country disseminating foul and calumnious falsehoods about scientific investigators, and it was a happy idea that prompted Mr. Paget thus to show a little of what research had done for modern medicine, and what sort of men investigators were. An accomplished writer and a vigorous opponent, Mr. Paget has many qualifications for the task, and on the whole he has carried it out well. We are delighted to see the book in its third edition ; we only wish it were the thirtieth. To those medical men who at present take no interest in the controversy it becomes almost a duty to make themselves acquainted with its chief features, and we say without fear of contradiction that if they read this book their eyes will be opened. The portrait often drawn of the anti-vivisectionist as an enthusiastic humanitarian with a certain want of discrimination, will be found to reflect but little the professional anti-vivisectionist. No lie is too base, no slander too outrageous, no insinuation too revolting for them to use of scientific investigators. Mr. Paget gives quotations from their speeches and writings which reveal human nature at its lowest and at its vilest, and we can only say that it is inconceivable that persons in a civilised country can so far be blinded by passion and prejudice as to adopt the methods and make the statements that are here recorded. The book is one that cannot be too widely circulated.

SAVAGE ON WATER EXAMINATION (*b*).

A perusal of this book satisfies us that the author has succeeded in his aim " to demonstrate the facts which are now established, and to bring the varied data into some sort of ordered relationship." He deals in turn with bacteria occurring in soil, sewage, and water, with the methods of examination, and the interpretation of the results, in a satisfactory manner. The atypical coli bacilli, which are the cause of so many differences of opinion, receive an amount of attention that shows a determination on the part of the author to leave no stone unturned to render his book as helpful as possible. The portions devoted to the bacteria in the excreta of different animals are particularly interesting, and the author has collated and compressed a vast amount of information on this subject, which soon reveals to the reader the present state of our knowledge in this direction.

As an adjunct to laboratory teaching this work will be found useful, and it will be of great service to bacteriologists desiring the latest information on the subject. Unfortunately the author appears to have a very small appreciation of the value of the chemical analysis of waters, which is to be regretted. Apart from this, however, the work is characterised by a broadness in tone and a just appreciation of the work of other men, while the author's researches on the bacteriological examination of water allow an amply justified assumption that the book is the outcome of a wide personal experience.

(*a*) "Lectures on Massage and Electricity in the Treatment of Disease." By Thomas Stretch Dowse, M.D., F.R.C.P.Ed., formerly Physician-Superintendent London Sick Asylum, &c. Sixth Edition. Revised. Bristol : John Wright and Co., 1906. 7s. 6d. net.

LITERARY NOTES.

DR. ELIE METCHNIKOFF has done well to republish his Harben Lectures in book form. "The New Hygiene," as he names the little volume, is one that will supply many stimulating thoughts to those who have only looked at the questions dealt with from the British point of view. These questions are chiefly those of personal hygiene—the hygiene of the tissues and of the alimentary canal and the hygienic precautions against syphilis—and they are treated with the grace and skill that one has learned to expect from the distinguished school to which the author belongs. If his views seem unduly optimistic on some points, enthusiasm is perhaps the best fault one can have.

WE have to welcome yet another new contemporary, and we do so very cordially. "Folia Therapeutica," as its name implies, will deal chiefly with new preparations and methods of treatment, and if the future numbers keep up to the level of the first one which has lately appeared, there should be a wide demand for it. Good original communications such as the editor has secured are always of value to the practitioner, and as the printing and get-up of the journal are particularly well done, this new literary recruit has everything in its favour.

THE prize of seventy-five guineas, with bronze medal of the Parkes' Memorial Fund for 1906, have been awarded to Surgeon-Major F. Smith, D.S.O., R.A.M.C., for his essay on the "Sanitary Requirements of Naval and Military Units in Peace and War : with suggestions for Complete Schemes of Sanitary Organisation suitable for both the Navy and Army.' The subject for the next competition is : "The Part Played by Blood-Sucking Insects in the Causation and Spread of Disease in Man, and the Measures to be recommended for the Prevention of such Diseases."

THAT extremely practical little book by Mr. Frederick F. Maccabe entitled "War with Disease," has already reached a second edition. It is one of the best publications on military hygiene that has ever been issued, and the warm thanks of many general officers have been accorded to the author, supplemented by purchases of large numbers of copies for distribution among the rank and file.

Since the efforts recently made to stem the tide of infant mortality, almost every manufacturer of children's food has issued a booklet descriptive of its composition and proper method of use ; and there can be little doubt that if these were instructions intelligently carried out a large proportion of the deaths which now occur from improper feeding would certainly be avoided.

The latest essay before us is entitled "Healthy Children make Happy Homes," issued by the Angier Chemical Co., and written naturally in support of Angier's Emulsion, which has been chiefly instrumental in bringing about the restoration to health of many a little one. It is a remedy for long approved by medical men in suitable cases and as the little book is essentially one for mothers, any of whom may have a copy free by writing for it direct to the Angier Chemical Co., Ltd., Snow Hill London, it affords us pleasure to mention the fact.

DR. T. N. KELYNACK, hon. secretary of the Society for the Study of Inebriety, and editor of the new quarterly *Journal of Tuberculosis*, has just passed for press a work on "The Drink Problem in its Medico-Sociological Aspects."

WE understand that Sir Almroth Wright, Professor of Pathology in the Army Medical School, Netley, is engaged on a work on "Therapeutic Inoculation."

MEDICAL NEWS IN BRIEF.

Inquest on a Medical Man.

An inquiry was held at Lutterworth, on February 19th, on the body of Dr. J. R. Ogle (55), who died on Monday morning.

The Coroner stated that it was a painful case, and although there was nothing doubtful as to the cause of death, it was advisable to hold a public inquiry.

Carrie Hippenstall (trained nurse), stated that she had been in attendance on deceased. He told her he had pricked his finger while out shooting.

Dr. H. E. Davies said he was called to see deceased, who complained of pain in the middle finger of his left hand. There was a slight redness and a slight swelling of the second joint, and in the centre a slight black mark, which witness thought at first was a thorn. On examining it with a magnifying glass, he found a small black puncture, but no thorn there Deceased stated that he had pricked his finger the previous Friday—he thought it was with a thorn—while out shooting. On Wednesday the swelling had increased all over the hand. and he opened the hand back and front. Witness continued to attend him to his death. The cause of death was blood-poisoning, caused by septic absorption from the accidental wound of the finger.

The Coroner said the deceased was a personal friend of his, and it was a sad occasion for him to have to hold that inquiry.

The jury returned a verdict of death from blood-poisoning, and the foreman said the jury endorsed all that had been said by the Coroner.

Sale of a Practice.

At the Manchester Assizes on February 5th, before Mr. Justice Lawrence and a jury, Dr. Henry L. Smith sued Dr. Haslewood, late of Slaidburn, Yorkshire, for damages for alleged misrepresentation in regard to the value of a medical practice. Mr. Byrne was for the plaintiff, and Mr. Langdon, K.C., and Mr. Greaves Lord were for the defence.

Counsel explained that for some ten years Dr. Smith was in practice in South Africa. In December, 1905, he got in communication with Dr. Haslewood, and subsequently an agreement was entered into in respect of the Slaidburn practice, which was said to be worth £400. After entering on the practice Dr. Smith ascertained that it did not correspond with the representation made to him ; that the receipts were much less than £400 a year, and that instead of it being an exclusive one, other medical men who resided at a distance came into the district.

In evidence the plaintiff stated that the purchase price was £400 for the practice, with an additional £60 for drugs. He found that the extent of the midwifery and vaccination practice had been exaggerated. The whole of the takings for last year, including public appointments, amounted only to £244.

In cross-examination, Dr. Smith admitted having written friendly letters to Dr. Haslewood after taking over the practice, but he did not complain, he said, because, having, as he supposed, no redress, he resolved to try and work up the practice.

When the case was part heard a consultation took place between the parties, and in the result Mr. Byrne stated that opportunity having been offered of examining the visiting lists, his client was satisfied that they provided an answer to the allegation of fraud. He was instructed to withdraw that charge unreservedly. Terms had been arranged, which would be endorsed on counsels' briefs.

Mr. Langdon said he accepted the withdrawal, accompanied as it would be by a judgment in the defendant's favour.

THE Royal London Ophthalmic Hospital (Moorfields Eye Hospital) has received a donation of £50 from the Grocers' Company.

Apothecaries' Hall of Ireland.

THE annual dinner of the Worshipful Company of Apothecaries of Ireland took place on Saturday evening at the Gresham Hotel. The Governor (Colonel Adye Curran) occupied the chair. The health of the King having been duly drunk, the Governor, in giving the toast of the Visitors, said that the qualification granted by the Hall was a most comprehensive one, and one which was in every way up-to-date, fully qualifying the holder in Medicine, Surgery, and Midwifery, and accepted alike by all the service. They were on the eve of a great revolution in University Education in Ireland, and he sincerely hoped and trusted that, whatever might be the outcome of it, the interests of the Apothecaries' Hall of Ireland may be safeguarded, and in the grand shuffle of cards about to take place, theirs, although, perhaps, the least card to be played, might prove to be a trump. The Very Rev. L. Healy, Sir Lambert Ormsby, and Mr. Gerald Byrne responded. The toast of the Apothecaries' Hall was given by Sir Charles Cameron, and responded to by Dr. Seymour Stritch.

Annual Meeting of the Leinster Branch B.M.A.

ON Saturday last the annual meeting of the Leinster Branch of the British Medical Association was held in the hall of the Royal College of Physicians, Kildare Street. The chair was taken by Dr. J. Craig, and was subsequently occupied by Dr. John Lentaigne.

The annual report stated that the Council had met four times during the year, and elected 13 new members. The branch membership on December 31st, 1906, was 341, as compared with 340 on December 31st, 1905. The Council regretted the death of Dr. Laffan, of Tara. The credit balance in the hands of the treasurer amounted to £28.

A resolution protesting against the proposed reduction of representatives on the Central Council of the United Kingdom was adopted on the motion of Dr. Poyse, seconded by Dr. Mortley.

Dr. J. Lentaigne, who was appointed President of the Branch for the forthcoming year, read a paper dealing with the Viceregal Commission Report on the Poor Law Reform in Ireland. In the course of an interesting address he said no event of greater interest or importance to the profession in Ireland had ever occurred than the appearance of the report of the Viceregal Commission on Poor Law Reform in Ireland.

The following officers were elected for the ensuing year:—President, John Lentaigne, F.R.C.S.,; President-Elect, J. Wallace Boyce, M.B.; Vice-Presidents, F. W. Kidd, M.D., Sir William Smyly, M.D.; Country Representative of Branch on Irish Committee, J. M. Kenny, M.B., Granard; Hon. Secretary and Treasurer, Professor White, Royal College of Surgeons, Dublin. Votes of thanks to the outgoing chairman and to Dr. Lentaigne for his address brought the meeting to a conclusion.

The Jamaica Earthquake.

Mr. W. Ralph Hall Caine has received, on behalf of the passengers of the steamship "Port Kingston" at a meeting held on board the ship and presided over by Lord Dudley, the following letter:—

"Board of Trade, Marine Department,
"7, Whitehall Gardens, London, S.W.,
"February 22nd, 1907.

"Sir,—I am directed by the Board of Trade to advert to your letter of the 1st inst., addressed to the President, forwarding copies of six resolutions passed at a meeting on board the Royal Mail steamship "Port Kingston," respecting the services rendered by Sir Alfred Jones, K.C.M.G., Doctors Arthur Evans and Neville Williams, Nurse Sarah Cross, and the master, officers and crew of the "Port Kingston" on the occasion of the earthquake at Kingston, Jamaica, on the 14th ult. In thanking you for forwarding copies of the resolutions in question to this department, the Board desire me to say that they very highly appreciate, not only the self-denying labours of those who so readily assisted in the work of succouring the unfortunate sufferers from the catastrophe, but also the courage and devotion displayed in rendering those services under most trying and difficult circumstances.—I am, sir, your obedient servant, WALTER J. HOWELL."

Birmingham Health Conference.

AN important conference of representatives of the Birmingham Health Committee and the Boards of Guardians of Birmingham, Aston, and King's Norton, took place on February 8th. There were present the Lord Mayor (Councillor H. J. Sayer), Alderman Sir William Cook, and the Medical Officer of Health (Dr. Robertson), representing Birmingham; Mr. J. W. Turner and Mr. C. Fletcher (Birmingham Board of Guardians); Messrs. T. O. Williams and J. North (Aston Board of Guardians), and Messrs. T. A. Bayley, F. Barlow, and Curtis (King's Norton). The point under consideration was the clause of the Act which makes it imperative for a midwife in certain circumstances to call in the assistance of a registered medical practitioner. The object of the meeting was to agree upon a plan by which midwives having charge of necessitous cases might secure the attendance of parish doctors in cases of urgency. Hitherto it has not been the general practice of medical men to act in such cases merely on the statement of a midwife that a patient cannot afford to pay a professional fee. It is hoped that in the near future arrangements may be made by which parish doctors will honour the request of the midwives just as they have done that of relieving officers.

Cerebro-Spinal Meningitis.

The Public Health Committee of the Stepney Borough Council report that a case of cerebro-spinal fever has occurred in that borough. The case was taken to hospital where the patient died three hours after admission. Every step is being taken to isolate any further cases that may occur. The Committee think the disease should be made a notifiable one, but that there should be uniformity of action throughout the metropolis in this direction.

Three additional cases of cerebro-spinal fever and two deaths were reported at Belfast on Saturday, making a total of 113 cases, of which 61 have proved fatal. Another death occurred in the city yesterday.

Last week's deaths from spotted fever in Glasgow numbered 20. There were 42 new cases during the week.

University Intelligence—London.

THE Treasurer of Guy's Hospital has received a bequest of £1,000, under the will of the late Dr. Charles James Oldham, of Brighton, for the purpose of endowing an annual prize in Ophthalmology at the Medical School. A further anonymous donation of £200 has also been received for the Fund of the Endowment of Medical Education and Research.

The following candidates have gained the Diploma in Public Health:—Major E. G. Browne, L.R.C.P. F.S.I., R.A.M.C., John G. Devane, M.B.R.U.I., Capt. A. Leventon, F.R.C.S.I., I.M.S., with honours, T. Nicol, M.B.Edin., with honours, M. J. Russell, F.R.C.S.I., Major G. W. Tate M.B.Dub. Univ., R.A.M.C., A. A. Woods, L.C.R.P. & S.I.

IN connection with the recent rejection by the Grimsby Immigration Board of three Russian labourers suffering from trachoma, the chairman of the Board has issued a notification that German shipping agents must be made to understand that all cases of trachoma which their officers refuse to pass for America must be likewise refused for England, and that the Home Secretary will be asked to take drastic action if after this warning cases continue to be sent merely with the object of securing the passage money.

THE Friedenheim Hospital (Home for the Dying), Swiss Cottage, has received a grant of £300 from the executors of Mr. Alfred Beit.

WEEKLY SUMMARY OF MEDICAL LITERATURE, ENGLISH AND FOREIGN.

Specially compiled for THE MEDICAL PRESS AND CIRCULAR.

RECENT MEDICAL LITERATURE.

Infection of Man with the Bovine Tubercle Bacillus.—Weber (*Deut. Med. Woch.*, December, 1906) reports some interesting and important observations on tuberculosis from the Berlin Board of Health. In 20 cases the bovine variety of tubercle bacillus was found, 15 times in the mesenteric glands, 5 times in the cervical glands. The bovine type of infection is found almost exclusively among children, and is usually a primary infection of the intestine or mesenterie glands, never giving rise to the anatomical picture of phthisis, and possessing a marked tendency towards spontaneous cure. Infection seldom occurs during the first year, during which the milk is usually boiled; 90 per cent. of the cases were in children under seven. No instances have been observed in which infection with the bovine variety was transmitted from one human being to another. Only a single case has been reported among adults. Weber concludes that the danger of infection of man with bovine tuberculosis is a real one, though insignificant compared with that from the human variety. D.

Air Massage.—Klapp (*Mun. Med. Woch.*, January, 1907) describes a new method of physical treatment which he calls air massage. It consists of a strong current of air which is directed against the desired part of the body by means of a nozzle. It has much the same effect as manual massage, but differs from it in that there is no friction. If a current of cold air be followed by one of hot air active hyperæmia is also produced. Good results are claimed. D.

Epidemic Cerebro-spinal Meningitis.—Westenhoeffer (*Berlin Klin. Woch.*, 1906), as the result of his researches in the recent epidemic of cerebro-spinal meningitis in Silesia, announces that there is constantly in the early stages a pharyngitis, due to the meningococcus. The adenoid tissue at the vault of the pharynx is chiefly affected; the meningococcus may be cultivated from the pharyngeal secretion and from the tissue. This pharyngitis is always present from the beginning, preceding the involvement of the meninges, and passes off in the course of a week or so. Westenhoeffer regards this as undoubtedly the port of entry of the meningococcus. The nose is only secondarily affected. The infection of the meninges takes place by way of the blood current, rather than directly by way of the lymph channels; for this route speak the cultivation of the cocci from the blood, and the presence of endocarditis, arthitis, encephalitis, etc. The meningococcus is also found in the pharynx of healthy persons, but only in those who have been exposed to the disease. Such cocci bearers are an important means of spreading infection, and should be isolated. The reason that children form the majority of those affected (90 per cent. in this epidemic) is that the adenoid tissue is more developed, and pharyngeal infections more common at this age. Moreover, the majority of adults sectioned by Westenhoeffer showed hyperplasia of the lymphatic tissue, so that in this respect they resembled children. D.

Treatment of Asthma.—Zuelzer (*Therapie d. Gegenwart, Berlin*) ascribes the asthmatic paroxysm to expansion of lung through irritation of the vagus nerve. That swelling of the mucous membrane of the bronchi and possibly bronchial spasm, contribute to the clinical picture, is not to be denied. That such an expansion of the lung can be produced by irritation of the vagus is easily proved by experiment. This experimental expansion of the lung can be cut short by the administration of atropin. Zuelzer, therefore, advises the administration of atropin by hypodermic injection for attacks of asthma. A dose of 1 mg., he states, causes a reduction in the limits of the lung within from 10 to 15 minutes, with marked improvement in the subjective condition. D.

Treatment of Nephritis.—Alberto Rovighi writes on this subject in the *International Clinics* (Vol. II., Sixteenth Series, p. 198). He reviews briefly the development of the treatment by decapsulation, and then reports the result of some experiments which he had made on animals, with a view to determining whether such treatment was of any value or not. Several rabbits were treated with cantharides and with diphtheria toxin, until the typical signs of nephritis had been produced. Some of these were then subjected to scarification of the renal capsule, some to unilateral, and some to bilateral decortication, while control animals were left unoperated on in each case. Out of the rabbits treated with the diphtheria toxin, all of the control rabbits, 10 in number, died, while five out of seven operated on recovered. Slightly better results were also obtained in the rabbits treated by cantharides, and later scarification, than in those left untouched after the poison had been administered. In the animals that recovered after operation, it was noticed at the autopsy a month later (the animals were killed by chloroform) that a new fibrous capsule had been formed, which contained numerous new blood vessels, and that these vessels anastomosed freely with the stellate veins on the surface of the kidney. Immediately after decortication there is an increase in the amount of urine passed, and a gradual disappearance of albumin and casts. Unilateral decortication seems to be attended by better results than the double operation, and this is attributed by the author to a renorenal reflex. The author also ascribes the beneficial results that he has noted to a modification of the renal circulation, leading to a better irrigation of the diseased organ with blood, and feels justified in recommending decapsulation in (1) cases of acute nephritis; (2) cases in which anuria and subsequent uræmia supervene in the course of chronic nephritis; (3) cases in which all medical measures have been tried and without success. M.

The Prophylaxis of Scarlatinal Nephritis.—Dr. Thompson has analysed the records of 300 cases of scarlatina with a view to determine whether drugs have any influence in preventing the onset or diminishing the severity of scarlatinal nephritis (*Edin. Med. Jour.*, February, 1907, p. 103). The drugs employed were urotropine, hexamethylene tetramine, and metramine, and the dose of each was 15 grains daily in divided doses, given from the commencement of symptoms of the fever. Forty-seven cases were treated with urotropine, and of these only one presented a slight transient albuminuria; 137 cases received hexamethylene tetramine, of whom 15 developed more or less severe nephritis, and 7 had transient albuminuria; 26 cases had metramine, out of which number three developed nephritis and one albuminuria; while out of 90 cases treated without drugs 8 developed nephritis and two albuminuria. The author's conclusion is that urotropine is decidedly of value as a prophylactic, and advises that it should be given in all cases for 28 days from the beginning of the disease. It should not be allowed, however, to interfere with the other precautionary means adopted, such as diet, avoidance of exposure, etc. M.

Treatment of Epilepsy with Food Poor in Nitrogen.—The older physicians were accustomed to feed epileptic patients on a diet containing little proteid, and in order to test the value of this, Voisin and Norero (*Rev. Mens. Des. mal de l'Enf.*, 1905, S. 252) have tried with some of their patients a diet composed of milk and vegetables. In addition the ordinary salt of the diet was replaced by the corresponding bromide. Simple removal of sodium chloride from the food without replacement by bromide was found to have no effect. Ten epileptic patients were kept on the low nitrogen diet for a period of four weeks, and then gradually various articles of proteid nature were added. The diet was well borne, but apparently had no special effect on the fits, as neither the number or character of these were altered. M.

Barberio's Spermin Reaction.—Lewinson (*Berlin Klin. Woch.*, 1906, No. 41) writes on this test, which is likely to prove of value in medico-legal work. According to Barberio, yellowish, needle-like, or rhombic crystals form in human serum, when Esbachs re-agent is added to it or to a concentrated watery solution. The reaction, according to the present writer, is probable specific for human semen, since the spermatic fluid of several animals, and of fish, had failed to react. Emulsions of human tissues also fail to react, and, on the other hand, it has been shown that the addition of chloroform or of formalin to the semen do not at all interfere with the crystal formation. In cases of Azoospermia the reaction was sometimes negative and sometimes positive, from which it is concluded that the reaction does not depend on the presence of the actual testicular secretion. It is more likely that it is due to the presence of the prostatic fluid. M.

Pathology of Paralysis Agitans.—Naka (*Arch. für Psych. u. Nervenkrank*, Bd. 41) has investigated the pathological anatomy of two cases of paralysis agitans, as revealed in the brain, spinal cord, some peripheral nerves, and some of the muscles. Apart from accidental changes, he found in the muscles a great increase in the nuclei, and in the nerves the same, along with very marked thickening of the peri and endoneurium. In the spinal cord the well known senile changes were found, namely, pigmentation of cells, thickening of the neuroglia, softening of the ependyma cells, together with obliteration of the spinal canal, and corpora amylacea. In the brain the writer found slight cell changes in the Rolandic area, and in Purkinjes cells. M.

The Treatment of Lupus Vulgaris.—Evans (*British Journal of Dermatology*, February, 1907) discusses the present state of the treatment of this disease in the light of the results that have been obtained by the more recent methods. For the purpose of forming a comparative estimate of the various methods of treatment, he classifies them under the following heads:—1. Application of caustics and scarification. 2. Scraping with or without the after application of caustics. 3. Excision. 4. Actinic treatment. 5. Opsonic treatment. For purposes of treatment the body may be divided into two regions, in the first of which may be placed the face and neck, and in the second the rest of the body. In treating cases in the first class not only is the cure of the disease of importance, but the nature of the scar resulting from such cure is also of the first importance. An unsightly scar on the face, especially in women, is almost as great a disability to the patient as the original disease. Dealing with cases in the second class is comparatively simple, for the conditions to be satisfied are only rapidity and completeness of cure. Evans is satisfied as the result of his experience that either the method of scraping or excision best satisfies these conditions, for none of the "actinic methods" can give results which can approach these in rapidity and certainty. In dealing with lupus of the face excision is rarely possible, and the scar left after treatment by scraping or caustics is usually most unsightly. Evans is unable to endorse the high claims advanced by some observers in favour of high frequency in the treatment of lupus. With regard to the Finsen method and the Röntgen rays, either method can give most excellent results. There is little to choose between the scars left after treatment by either of these methods, although it has been claimed that the scar left by the Finsen light is softer and thinner than that left by the other method. Both methods appear to be equally thorough. Evans is inclined to think that recurrence may be more likely after the Finsen treatment, since the power of penetration is less than that of the X-rays. In regard to rapidity of action, the X-rays are much superior, and since a much larger area can be treated at one time, the duration of treatment is much less than with the Finsen method. With regard to the treatment of tuberculin, its use is especially indicated in cases where the area is large or the tendency to recurrence is great; but the number of cases for which it is suitable is limited, and even when it seems the best treatment the X-rays form a useful adjunct. K.

A Case of Multiple Leiomyomata of the Skin.—Beatty (*British Journal of Dermatology*, January, 1907) describes a case of this rare condition of the skin, of which only twenty-six cases have previously been described. The patient was a young man, æt. 28, who complained of an eruption on the left side of the forehead, on the front of the chest, and on the left upper extremity. The eruption had been present five years, but no very reliable account of its onset could be obtained. The patient thinks that the eruption first appeared on the chest and then on the face; the nodules all came out together and not in crops; in fact, the whole condition seemed to start at once, but gradually became more pronounced; there has been no increase during the past year. There are no subjective symptoms except some smarting when exposed to severe cold. The colour of the nodules is pale pinkish red, or that of the normal skin, and in size they vary from 2 to 4 mm. in diameter. In some places they are conglomerate, or run in the lines of the hair follicles to form ridges, but for the most part they are distinct from one another. They are firm in consistence, but not of cartilaginous hardness as described by Krzysztalowiez in his case. Histological examination of a nodule excised from the forearm showed the structure to be that of a leiomyoma. The mass of the myoma is in the deeper part of the corium, but in a few places narrow strands of muscle cells ascend obliquely from the main mass almost to the epidermis. In a few sections there was a thick muscular bundle close to a sebaceous gland and portion of a hair. This bundle was evidently part of the myoma, but no connection could be traced between it and an arrector pili. Beatty is inclined to think, though he was unable to prove, that the myoma has origin from the arrectores pilorum. K.

Paralysis of the Abducent Nerve.—Wilner (*Archives of Pediatrics*, January, 1907) describes the case of a child, æt. 9, who, while recovering from an attack of influenza, got an acute otitis media. The ear continued to discharge freely for several days, but the temperature varied between 99° and 104° F. The child complained of great pain in the side of the head, and a week after the onset of the otitis became drowsy, and developed an internal strabismus of the right eye. For some twenty-four hours the child remained somnolent and apathetic, temperature 99° F., and pulse irregular, and varying from 90 to 60. After remaining in this condition for about forty-eight hours, the child began to improve, and progressed to complete recovery, but the paralysis of the external rectus muscle did not finally disappear till about three months later. K.

Royal Army Medical Corps (London Companies).

MAJOR-GEN. LORD CHEYLESMORE recently presented the prizes at the Headquarters, Calthorpe Street, W.C. Col. V. Matthews, officer commanding, said the past year was the first since 1900 in which they had not actually lost in strength. Seventy-seven recruits were enrolled, as against 55 last year, and the strength of the companies totalled 312, as against 305. A vote of thanks was passed to Lord Cheylesmore on the motion of Col. Sloggett, P.M.O. of the corps in the London District, seconded by Col. J. Cantlie, M.B.

NOTICES TO CORRESPONDENTS, &c.

☞ **Correspondents** requiring a reply in this column are particularly requested to make use of a *Distinctive Signature or Initial*, and to avoid the practice of signing themselves "Reader," "Subscriber," "Old Subscriber," &c. Much confusion will be spared by attention to this rule.

Original Articles or Letters intended for publication should be written on one side of the paper only, and must be authenticated with the name and address of the writer, not necessarily for publication but as evidence of identity.

Reprints.—Reprints of articles appearing in this journal can be had at a reduced rate, providing authors give notice to the Publisher or Printer before the type has been distributed. This should be done when returning proofs.

SUBSCRIPTIONS.

Subscriptions may commence at any date, but the two volumes each year begin on January 1st and July 1st respectively. Terms per annum, 21s.; post free at home or abroad Foreign subscriptions must be paid in advance. For India Messrs. Thacker, Spink and Co., of Calcutta, are our officially-appointed agents. Indian subscriptions are Rs. 15.12.

ADVERTISEMENTS.

For One Insertion:—Whole Page, £5 ; Half Page, £2 10s. Quarter Page, £1 5s.; One-eighth, 12s. 6d.

The following reductions are made for a *series*:—Whole Page, 13 insertions, at £3 10s.; 26 at £3 3s.; 52 insertions at £3, and pro rata for smaller spaces,

Small announcements of Practices, Assistancies, Vacancies, Books, &c.—Seven lines or under (70 words), 4s. 6d. per insertion; 6d. per line beyond.

Sional.—If X bought the practice on the understanding that the appointments would be transferred as you say, he went beyond what caution would require. Y obviously could only do his best to obtain transference, and if he has failed in the case mentioned it would be graceful on his part to remit the purchase money in respect of it. The agreement should have been so worded as to cover the point, namely, that if the appointments were not obtained the purchase money would be proportionately reduced. On the facts stated, we think X would not have any legal ground for action, and we should advise a compromise on the lines suggested, namely that Y should remit the £75 (*i.e.*, £50 at one and a-half years' purchase), the amount earned during the period of introduction being equally shared.

ANOTHER CURE-ALL GONE WRONG.

At an Extraordinary General Meeting of the members of the Oneida Medicine Company, Limited, held at the registered offices of the Company, in London, a few days since, the following Resolution was duly passed:—

"That it has been proved to the satisfaction of this Meeting that the Company cannot, by reason of its liabilities, continue its business, and that it is advisable to wind up the same, and that accordingly the Company be wound up voluntarily." The public would appear to need-a-medicine the Oneida Medicine Company failed to supply.

DR. PATON AND THE MEDICINE MEN.

The life of Dr. Paton, the famous missionary to the New Hebrides, whose death was recently announced, was crowded full of struggle and adventure, and narrow escape among the savage races of the Pacific. Again and again his life was in danger. Very striking is the story of how he defied the medicine men to kill him by magic. First they offered to kill him on the spot by incantations and rites. They set to work, and Dr. Paton looked on smiling and not a whit the worse. Then they said they would kill him within a week, as they had not enough medicine men on the spot to do it right away. Dr. Paton told them to set to work as hard as they liked, and get as many magic men as they liked, but that he would turn up alive next Sunday. The witch-doctors worked their hardest during the week at all sorts of death-dealing rites; but when Dr. Paton appeared on the Sunday, alive and well, they had to confess themselves beaten. They declared that Dr. Paton must be a magic man also, and that his God must have been stronger and beaten their gods.—*Aberdeen Evening Gazette.*

Romanus.—The person named is not on the medical register, nor has he ever been. Does he describe himself by any title implying that he is a medical man?

THE GRUB HABIT.

The Islington coroner, at an inquest recently, asked a witness if the deceased had been in the habit of taking drugs.

Witness: Very much, sir.
The Coroner: What kind of drugs?
Witness: Oh, I thought you said grub.

Meetings of the Societies, Lectures, &c.

Wednesday, February 27th.

Hunterian Society (London Institution, Finsbury Circus, E.C.).—8.30 p.m.: Pathological Meeting.

Medical Graduates' College and Polyclinic (22 Chenies Street, W.C.).—4 p.m.: Mr. M. White: Clinique. (Surgical). 5.15 p.m.: Lecture:—Dr. G. H. Savage: The More Recent Treatment of the Insane.

North-East London Post-Graduate College (Tottenham Hospital, N.).—2.30 p.m.: Cliniques:—Dermatological (Dr. Meachen), Ophthalmological (Mr. Brooks), Medical Out-patient (Dr. Whipham).

Thursday, February 28th.

Medical Graduates' College and Polyclinic (22 Chenies Street, W.C.).—4 p.m.: Mr. Hutchinson: Clinique. (Surgical) 5.15 p.m.: Lecture:—Dr. B. Abrahams: Some Common Types of Neurasthenia.

North-East London Post-Graduate College (Tottenham Hospital, N.).—2.30 p.m.: Gynæcological Operations (Dr. Giles). Cliniques: Medical (Dr. Whiting), Surgical Out-patient (Mr. Carson). 3 p.m.: Clinique:—Medical In-patient (Dr. Chappel). 4.30 p.m.: Lecture:—Mr. Cantlie: Demonstration in Relation to Tropical Disease.

St. John's Hospital for Diseases of the Skin (Leicester Square, W.C.).—6 p.m.: Chesterfield Lecture:—Dr. M. Dockrell: Ul-erythema: I., Centrifugum: II., Telangiectic; III., Ophryogenes.

Association of Certificated Dispensers (Apothecaries' Hall, Blackfriars, E.C.).—7.30 p.m.: Address:—Dr. F. S. Toogood.

Friday, March 1st.

Medical Graduates' College and Polyclinic (22 Chenies Street, W.C.).—4 p.m.: Dr. E. Waggett: Clinique. (Ear).

North-East London Post-Graduate College (Tottenham Hospital, N.).—9.30 a.m.: Clinique. Surgical Out-patient (Mr. H. Evans). 2.30 p.m.: Surgical Operations (Mr. Edmunds). Cliniques:—Medical Out-patient (Dr. Auld), Ophthalmological (Mr. Brooks). 3 p.m.: Clinique:—Medical In-patient (Dr. Leslie).

West Kent Medico-Chirurgical Society (Miller Hospital, Greenwich Road, S.E.)—Clinical Evening.

Vacancies.

New Saughton Hall Private Asylum, Polton.—Resident Assistant Medical Officer. Salary £120 per annum, all found. Applications to Medical Superintendent.

Leeds General Infirmary.—Resident Surgical Officer. Salary £150 per annum, with board, residence, and washing. Applications to the Secretary of the Faculty.

York County Hospital.—House Surgeon. Salary £100 per annum, with board, residence, and washing. Applications to Frederick Neden, Secretary and Manager, York.

London Open-Air Sanatorium, Pinewood, Wokingham, Berks.—Assistant Resident Medical Officer. Salary £100 per annum, all found. Applications to the Secretary, London Open-Air Sanatorium, 20 Hanover Square, London.

Bristol General Hospital.—Bacteriologist. Salary £240 per annum, Applications to the Secretary at the Hospital. W. Thwaites, Secretary.

Galway Hospital.—Resident Medical Officer and Compounder of Medicine. Salary £75 a year, with apartments and rations. Applications to S. J. Leonard, Clerk.

Appointments.

Coates, Charles Joseph 'Adams, L.R.C.P. and S.Edin., L.F.P.S. Glasg., District Medical Officer by the Shepton Mallet (Somerset) Board of Guardians

Drury, W. H., L.R.C.P. and S.Edin., L.F.P.S.Glasg., District Medical Officer to the West Ham Board of Guardians.

Jenkins, T. J., L.R.C.P.Lond., M.R.C.S., House Surgeon at the Cardiff Infirmary.

Lockyer, Cuthbert, M.D., B.S., F.R.C.S., M.R.C.P., Consulting Gynæcologist to St. Mary's Hospital for Women and Children.

Martineau, A. J., F.R.C.S.Edin., Honorary Surgeon to the Throat and Ear Hospital, Brighton.

Milne, Mearns A., M.B., Ch.B.Aberd., Medical Officer to the Montrose Parish Council.

Ogg, A. W. T., L.R.C.P. and S.Edin., L.F.P.S.Glasg., Medical Officer of Health for the Burgh of Rothes, Morayshire.

Rees, Morgan James, M.D.Lond., L.R.C.P., M.R.C.S., D.P.H.Lond., Medical Officer of Health of Aberdare.

Scatliff, H. H. E., M.R.C.S., L.R.C.P.Lond., Assistant Surgeon to the Brighton and Hove and Sussex Throat and Ear Hospital.

Births.

Morley.—On Feb. 22nd, at 45 High Street, Portsmouth, the wife of G. F. Morley, M.R.C.S., of a son.

McClure.—On Feb. 24th, at 9 Newton Place, Glasgow, the wife of J. Campbell McClure, M.B.—a son.

Walker.—On Feb. 20th, at "Sunbury," Dormans Land, Surrey, to Dr. and Mrs. H. J. Davey Walker—a daughter.

Marriage.

Sargent—Ashman.—On Feb. 21st, at the Congregational Church, Sneyd Park, Bristol, Percy W. G. Sargent, M.A., M.B., B.C., F.R.C.S., of Harley Street, London, eldest son of Mr. and Mrs. E. G. Sargent, of Pembroke Road, Clifton, to May, youngest daughter of Sir Herbert and Lady Ashman, of Cook's Folly Bristol.

Death.

Dow.—On Feb. 19th, at St. Luke's Hospital, Constance, widow of the late James A. Dow, Esq., late of the Accountant-General's Department of the Admiralty, and third daughter of the late George Lewis Cooper, Esq., F.R.C.S.Eng., in her 60th year.

INCORPORATED DENTAL HOSPITAL
OF IRELAND, DUBLIN.

The Board of Governors of this Hospital require the services of Medical Gentlemen to act as Anæsthetists, also the services of Qualified Dentists, to fill the Office of Prosthetic House Surgeon, Assistant House Surgeon, and Extra Assistant Dentists to the Hospital.

Applications to be forwarded on or before Saturday, March 2nd, 1907, to
WILLIAM ATKIN SHEA, J.P., Registrar,
from whom all information may be obtained.

THE MEDICAL PRESS AND CIRCULAR.

"SALUS POPULI SUPREMA LEX."

VOL. CXXXIV. WEDNESDAY, MARCH 6, 1907. No. 10

NOTES AND COMMENTS.

A New Old Bailey.

THE opening of the new buildings of the Central Criminal Court for London last week was made the occasion of much rejoicing and junketing. A magnificent pile of great architectural pretensions has been made to replace the historic Old Bailey, where the last scene but one of a thousand sordid tragedies has been played out under the limelight of legal effulgence and vulgar curiosity, and the presence of the King himself was obtained to give splendour to the inaugural ceremony of the new Court. With the usual fanfare of trumpets and the accolade of knights, the doors of the splendid building, which cost over a quarter of a million sterling, were opened for the trial of the miserable wretches whose crimes against society form the chief item on the menu of the halfpenny press. It is a curious commentary on the mental attitude of people towards crime that the erection of a huge and costly building for the trial of malefactors should be considered a praiseworthy civic achievement, and still more so that its opening should be made the occasion of a Royal progress and general hilarity. While thankfully acknowledging that the administration of justice in the British Isles is probably purer and fairer than in any other country, one cannot but consider it a bitter sarcasm on a thousand years of civilisation that gross crime in the community should require larger accommodation for its sifting, and that there should be feelings of joy over an event of the kind. Surely if the health and morality of a country—for they are almost synonymous—were scientifically organised and catered for, a reduction of the machinery for the trial of offences would be regarded as progress, and the demolition of criminal courts hailed with delight. But till the educative mission of hygiene has advanced very considerably we shall presumably continue to plume ourselves on the architectural dignity of new old Baileys.

Sic itur ad astra.

THERE is no man who has to smile his way through the world like the medical practitioner, and no man to whom the external appearance of success means so much. The doctor lives upon his credit with his fellows more than anyone else, and however low the state of his finances, he knows his only chance of keeping up is to assume an air of prosperity. How many aching hearts and empty pockets there are behind brass-plates and red lamps, no one knows. A pathetic instance of the narrow margin on which many a medical man works came to light last week, when a removal order was applied for at Newport in the case of an inmate of the workhouse there. This inmate, it turned out, was a medical man holding university degrees, who for some years had been medical officer to the workhouse at Eastry (Kent), and, later, district medical officer to the guardians of the same place, but who, through ill-health and increasing competition, had lost his appointments and practice, and been reduced to penury. By the irony of fate he now finds himself transferred as a pauper to the very workhouse which he had served as a medical officer.

Crocker v. Doyen.

JUDGMENT has at last been given in the case of Crocker *versus* Doyen. The Court, after a long trial, found that the contract was freely entered into by Mr. Crocker; that even if the fee (100,000 francs) was exaggerated, the plaintiff consented to pay that sum, and as the contract did not violate any legal principle, it could not be set aside; that no undue pressure on the mind of Mr. Crocker was used by Dr. Doyen; and that if the full contract was not carried out, it was through Mr. Crocker's own action in taking his wife away from France. No one, we imagine, will be disposed to quarrel either with the law or the common-sense of this decision. If a man believes wild statements made by irresponsible people, and pays money on the strength of them, he has only himself to thank if he is disappointed in his bargain. Dr. Doyen, in spite of his vagaries, remains a legally-recognised practitioner, and the principle of "no cure, no pay" is not one sanctioned by the profession. American millionaires will find in their own country surgeons as competent in the treatment of cancer as any we know of in France or elsewhere. If they wish to indulge in fancy treatments, well, they must pay the piper.

Sanitary Jaunts.

THE pleasant *fetes champetres*, which are held every summer by certain scientific and other learned bodies, are something of a tax on the hospitality of municipalities, and even the payment of the expenses of representatives sent by other towns is a "burden" on the rates which is apt to be adversely commented on. We are not therefore surprised to find that the canny Scots, after a good deal of subterranean grumbling, are banding themselves together in an attempt to secure that their siller shall be laid out to the best advantage. The two chief hygienic organisations, the Royal Sanitary Institute and the Royal Institute of Public Health, have, nominally, precisely the same objects, but owing to certain differences in *personnel* each prefers "to keep itself to itself," as the saying goes. By this duplication of machinery a good deal of extra expense is involved, and as each body holds an annual congress to which representatives of all sanitary authorities are invited, neither can afford to let the attractions of its gatherings fall below the level of the other. The town councils of the chief Scottish towns have begun to show signs of striking at having to pay each year for two separate jaunts for its officers and representatives, and a joint meeting was held last week with the object of prevailing on the two institutions to hold either combined congresses, or alternate ones. If any alteration be brought about as the result of this action, we fancy from what we know of the two institutes that it is likely to take the latter than the former shape.

This Way Madness Lies.

FAITH can not only remove mountains and heal the sick, but also, on the evidence of Dr. Ormsby, police surgeon of Dover, cause insanity. Last week a man who appeared before the Dover magistrates was found to be a lunatic, the mania from which he was suffering having developed since he became connected with a sect of Faith Healers who practise their ministrations in that town. Dr. Ormsby, in giving evidence, said that the man was insane, and he was the third person connected with the sect who had been similarly affected during the last fortnight. The Faith Healers, he thought, had "a knack of sending people mad at Dover." That is no doubt the case, but an even more important deduction would seem to be that it is from persons of weak intellect that the ranks of Faith Healers are recruited. Like the physician in Macbeth, this sect seems to find its sphere of successful activity severely restricted to corporal ailments.

A Toothsome Morsel.

AN extraordinary case was recently tried at Manchester Assizes, wherein a widow, described as a greengrocer, confectioner, and holder of an "off" license, sued William and Ada Grundy, described as "dentists" for the loss of her daughter through their alleged negligence in extracting her teeth. The child, who was not quite nine years old, was taken by her mother to the defendants to have some teeth out, and according to her theory, one of the teeth was swallowed during the operation, with the result that fatal pneumonia was set up. According to the mother's evidence, the operation was a sort of family affair, a bedroom chair being brought in, Mrs. Grundy holding the child's head, and the maid-servant her hands, while Mr. Grundy pulled out the teeth. Three were asserted to have been extracted, and the modest fee of 1s. 6d. only was demanded, a rebate of a penny per tooth being made in favour of the patient. The mother, Mrs. Wells, was anxious to retain the trophies of the operation, and a search was made on the floor, but only one tooth could be found. Mr. Grundy suggested the pup might have swallowed the remainder, which Mrs. Wells thought was "a funny thing," adding naïvely, "they'll be bad to digest." As the child was taken ill that day and died of pneumonia, the conclusion was come to that she must have inhaled the missing teeth. In the absence of post-mortem evidence, the point was a delicate one to decide, and the dog being unable to give evidence, the matter balanced about the credibility of the lady-greengrocer's theories and those of Mrs. Grundy's husband.

Unconscientious Objectors.

A CONTEMPORARY, in discussing the recent vaccination debate, relates an interesting story told to Mr. Labouchere by Mr. John Bright. The latter was staying with the Duke of Argyll, and one day, while talking to a keeper about breeding terriers, he was informed that there was great difficulty in rearing them owing to the ravages of distemper. Mr. Bright advised the man to vaccinate them, and was astonished to hear some years later that his suggestion had been carried out, and had produced a highly beneficial effect on the infantile mortality among the Duke's terriers. We do not know whether the procedure would be regarded as coming under the ban of the Home Office, but, if not, it would be interesting to have the experiments repeated. There is no particular reason in pathology why vaccine-lymph should protect puppies from distemper, but as its initial trials in the human subject were empirical, it might be found that keeper's experience was in accordance with some law undreamed of in our philosophy.

LEADING ARTICLES.

THE HEALTH OF DUBLIN.

THE report of Surgeon-Colonel Flinn to the Local Government Board for Ireland on the sanitary conditions of Dublin, to which we draw attention in another column, is the most important document bearing on the subject since the report of Lord Cadogan's Committee was published in 1900. The citizens of Dublin are so accustomed to a death-rate constantly among the highest in Europe, that they have come to regard it almost as a natural phenomenon, with which it is useless, if not indeed impious, to attempt to tamper. They must learn that, until the Public Health Authorities have done all in their power to improve the health of the city, its high mortality must be regarded as due not to natural causes, but to wilful neglect. The present report, in its terse official language and in its obvious attempt to avoid exaggeration, is in fact the most scathing indictment of the Health Authorities which could be made out. In 1900 Lord Cadogan's Committee made eighteen recommendations for the improvement of the health of the city. Some of them were of far-reaching importance, some were matters of detail, but nearly all of them were adopted formally by the Public Health Committee of the Corporation of Dublin. Of the eighteen, four have been carried out; five more have to some degree or other been acted on; but, let our readers observe, no attempt has been made to meet the other nine. It is to be noted that these recommendations have not been rejected, but merely that they have been shelved. Amongst them is the suggestion that an assistant medical officer of health should be appointed, who should give his whole time to the duties of the office. It can hardly be expected that one gentleman, however untiring, who does not give his whole time to the duties of the office, is sufficient to attend to the entire sanitary administration of such a city as Dublin. It is true he has the assistance of the "District Medical Officers of Health" — the dispensary medical officers of the city—but their sanitary duties are entirely secondary to their other work, and are requited on that understanding. We doubt if there is another city in the kingdom of the size of Dublin which is without a single whole-time medical officer of health. It is time for the citizens of Dublin to stir themselves. The callous contempt for their lives shown by the Corporation of Dublin, should long since have spurred them into activity. The success of the Health Party at the recent elections in Belfast shows what can be done if once interest is roused. We believe, moreover, that nothing less than radical reform is necessary. Nothing should be allowed to stand in the way of ridding Dublin of its present reputation of being the most unhealthy city in the kingdom. In this matter, too, the medical profession of Dublin have a responsibility to fulfil. It is their duty to see that the public is made fully aware of the present scandalous condition of affairs, and to point out the path of reform.

CORONERS' FEES AND HOSPITAL MEDICAL WITNESSES.

THE usages that spring up in the course of time around a profession are often of an anomalous and indefensible nature. The fact is perhaps hardly to be wondered at, for after all practice must necessarily be moulded more or less upon precedent in all law-abiding communities. Whether the usages and the injustice spoken of are to be at the expense of the public or of any particular profession depends to a great extent upon the organisation of the latter. Lawyers, for instance, have always shown themselves able to protect their own corporate interests to the uttermost degree, but when we turn to medical men we find that in many ways they allow their rights to be unduly trespassed upon. In this place we wish to advert to a single injustice, namely, the refusal of coroners to pay the fees of an expert witness to any medical man giving evidence in his capacity of honorary or paid medical officer of a hospital. The point was raised not long ago at Weybridge, where Dr. Howard Wilson demanded a fee for giving evidence in a case where a patient died in a cottage hospital. It should be noted that this institution had no honorary medical officer, and that any medical man was entitled to charge patients for attendance therein. In face of these facts the Surrey coroner, Mr. G. Roumieu, declared his inability to pay any fee. In the most candid way imaginable he admitted that this state of affairs is nothing short of a scandal. "In a case of this kind," he said, addressing Dr. Wilson, "you follow the man to the hospital, but if you had sent him to his own home and attended him there you would have been entitled to a guinea for giving evidence. It seems a great anomaly that I cannot pay you because you sent him there, thinking it was the best place for him. You come here, lose your time, and are debarred from getting your guinea. It is an injustice, but it is the law." In ordinary voluntary hospitals neither paid nor honorary medical officers get fees for evidence in the coroner's court. Hence the curious fact that if a patient dies on the way to hospital the house surgeon or house physician gets a guinea for attending the inquest, whereas he would be entitled to no fee if the person gave any sign of life after entering the gates of the institution. The history of how the anomaly arose was ably sketched out by Mr. Roumieu;—

"Before 1835 medical men were never paid at all for attending inquests; but about that time a Bill was introduced in the House of Commons by the coroner for Middlesex to make provision for the payment of doctors for giving evidence at inquests and for making post-mortem examinations. There was a terrible outcry. People said it would be a great tax on the rates if doctors were paid in all cases. People were taken in many cases of accident to the hospitals, and in the large hospitals of London especially; there were in consequence a great many deaths in comparison to the populations of the districts in which they were situated. Many inquests were held in these institutions, and the payment of doctors in hospitals, it was said, would lead to a heavy charge on the rates. In order not to jeopardise the passing of the Bill, the member who introduced it agreed to a section being added, excluding the cases of people who died in hospitals and public institutions 'supported by voluntary contributions or otherwise.' These words embraced a great deal. At that time cottage hospitals were not thought of any more than were motor-cars. Cottage hospitals had been introduced, and they were the most valuable and useful institutions possible. If cottage hospitals had been in existence in the days of William IV. they would in all probability not have been included in the clause relating to hospitals. Doctors in any of the large hospitals and lunatic asylums were not paid; but coroners paid doctors who were engaged in workhouse infirmaries, because there was an allusion in the particular section of institutions which were paid for and maintained out of the rates. It had been held that a workhouse or a workhouse infirmary was not a public institution. This was an anomaly, but there it was."

So far as the workhouse resident and other medical officers are concerned, we would respectfully call the attention of the Home Office and of the Local Government Board to the absolutely illegal way in which their fees at inquests are often withheld, often under unlawful pressure from the guardians, who not unfrequently make compliance with this illegality a condition of engagement. The matter, as we have often insisted, deserves the attention of our professional Defence Unions, and of the British Medical Association.

CURRENT TOPICS.

The Trailing Skirt.

AMONG the evergreens of current journalism none has a hardier growth than that of the trailing skirt and its dangers to health. Nor can it be denied that in this particular trade the ready writers of Fleet Street have science on their side. As a collector and distributor of germs it would be hard for the most perverted ingenuity to devise a more effective agency than a long trailing feminine skirt. For that matter the whole skirt, quite apart from its nether fringe, is a contrivance the existence of which it would be difficult to justify on common-sense grounds. In China womankind wear nether garments precisely and exactly corresponding to those of man, and no one is a bit the worse for it, while the Chinese woman gains in freedom and elegance of movement, to say nothing of the shifting of the weight of the clothing from the hips to the shoulders. But if fashion decrees that long skirts are to be worn by civilised Western women, then, science or no science, they will continue to sweep the pavements of our streets and the floors of our houses. In Prague the Sanitary Committee of the Municipal Council has forbidden ladies to wear long trains to their dresses. The death-rate of the city is excessive, owing chiefly, it is said, to a bad water supply. To attempt to reduce mortality from such a source by the curtailing of a minor distributing agency would strike the average English sanitarian as seizing the stick at the wrong end. For all that, it is to be hoped that the men of Prague will be able to enforce their sanitary views upon their wives and daughters. In this country a similar step would probably within a week lead to a revolution before which the recent revolt of the suffragettes would shrink to the level of mere child's play.

The Mosquito "Torture Trough."

LAST week the antivivisectionists of Manchester were moved to tears by a gentleman from Leeds who had visited the Pasteur Institute of Paris. With much power of literary expression he described the monkeys, dogs, rabbits and smaller animals that were being subjected to scientific observation and experiment. This sapient gentleman, however, came to the conclusion that all this work was done by men who could not really claim to have alleviated human suffering one iota. We wonder if the lecturer had ever seen a human being dying from hydrophobia. The sight is a terrible one, and once seen would probably reconcile him to the sacrifice of a thousand lower animals could the disease be thereby lessened or counteracted. It is well known amongst medical authorities that a large proportion of cases treated at the Pasteur Institute recover, especially if taken there soon after inoculation. Against that overwhelming expert verdict the Leeds "lecturer" pits his unskilled opinion. A trifle of that kind, however, does not stay the hand of the antivivisectionist when on the warpath. To the medical philosopher human life is sacred and all other forms of life subordinate. Indeed, that expresses the ultimate belief of the antivivisectionist when he sits at the dinner table or goes out in search of sport. It is only when medical men want to make researches with the view of preventing human maladies that the antivivisectionist grows excited. As a rule he would not hesitate to kill a mosquito or other venomous insect at sight. Yet an antivivisectionist witness before the Royal Commission last week gravely declared herself against experimentation upon mosquitoes. The human antivivisectionist is the vivisector, inasmuch as he wishes to circumvent the series of venomous and fatal inoculations which nature has placed it in the power of many lower creatures, as, for instance, the mad dog, the plague-infected rat, and the malaria-laden mosquito, to inflict upon mankind. Meanwhile the antivivisectionist artist may find a capital subject for his artistic pen in picturing the "mosquito torture trough."

The Embarrassment of the Pasteur Institute.

THE Pasteur Instute is labouring under a trial of essentially Gallic complexion. A gentleman with the classical name of Osiris lately enriched that abode of scientific research and treatment with a legacy of one million pounds sterling. As a matter of fact, after all claims on the estate were settled, the amount available to the Institute was reduced to the comparatively modest sum of £120,000. Even the latter reduced amount, however, has furnished certain friends of the Pasteur Institute with the materials for a Jeremiad. Excess of wealth, so runs their lament, is fatal to scientific effort, in proof whereof they instance the illustrious Pasteur himself, who began with nothing and accomplished everything. That is very well so far as it goes. Some of the world's greatest scientific achievements have been accomplished by poor men working upon scanty means. Modern scientific research, however, often demands an extensive outlay of money. Indeed, the necessity of endowment of scientific research by the nation has become an accepted axiom among most modern political economists.

Emergency Beds at Hospitals.

THE rejection of urgent cases by large general hospitals is always a serious matter, opening the door, it does, to the possibility of public scandal no less than of injury to individual sufferers. A writer in a lay contemporary has recently raised the question in a pointed way by referring to a case in which the poor woman who was bleeding internally "was refused by three or four London hospitals on the ground that all the beds were full." Without discussing the merits of this particular incident few who are acquainted with hospital life in the United Kingdom will deny the possibility of such an occurrence. The evil appears to arise from the want of close supervision of the nature of the cases and the social position of the patients occupying the beds of our charitable hospitals. Were chronic and other maladies unsuitable for hospital treatment carefully weeded out the pressure upon the wards would be lessened, not to mention the further relief that would be afforded by the exclusion of patients who should be paying their own private medical attendants in their own homes. In any event every properly organised general hospital should reserve a certain number of beds, say one in twenty, for emergencies, and for those alone. By strict adherence to this simple method many distressing scandals would be averted.

A Poor Law School Scandal.

MR. LOCKWOOD, the Local Government Board inspector, has made a report of the West Ham Workhouse School that recalls the scandals of Bumbledom in its worst days. Owing to inadequate laundry arrangements blankets and counterpanes were piled for months in a corner waiting to be washed. In one dayroom, 28 ft. by 16 ft., as many as 200 boys were sometimes congregated. In the infants' feeding room, 27 ft. by 18 ft., used sometimes also as a sleeping room, 109 infants were seen at dinner, with twelve small boys sitting on the floor. From amongst other sensational statements the following may be selected :—"There is no receiving ward for children coming in. The superintendent informed me that they are never without many cases of infectious diseases, such as measles, chicken-pox, scabies, ringworm (thirty-two cases now), and ophthalmia, besides such as are sent away, as scarlet fever, etc.; and that it is not possible in the space available in the infirmary to separate the infectious cases; so that he has known instances of children coming into the infirmary with one complaint, such as ringworm, being infected with measles by the measles patients already there."

Cerebro Spinal Fever.

FRESH outbreaks of epidemic cerebro-spinal meningitis continue to be reported from various parts of the United Kingdom. It will be interesting to watch the progress of the malady in Leicester, which has been recently invaded, inasmuch as that ancient town has pinned its faith to sanitation alone in the fight against small-pox. If its practical hygiene standard be this ideal Leicester ought to suffer lightly from cerebro-spinal fever, which is a disease of over-crowding and bad environment. London appears to be waking up to the seriousness of the situation. The County Council has approved the recommendation of the Public Health Committee to make the malady notifiable for six months. It has further decided to spend £200 for the taking of precautionary measures against the spread of the disease. The Port Sanitary Authority of London has also decided to include cerebro-spinal meningitis amongst the notifiable infectious diseases. There have been already several deaths from that cause in the metropolis and cases are under treatment at various general hospitals. The outlook, therefore, has considerably increased in gravity during the past week.

PERSONAL.

DR. MERYN GORDON, Dr. HOUSTON, and Professor P. F. FRANKLAND, F.R.S., have been called in to advise on the Belfast water supply.

MR. EDGAR H. BROWNE took the chair at a meeting at Liverpool, held with the object of forming a local committee in connection with the approaching second International Congress on School Hygiene.

MR. WATSON CHEYNE will open a discussion to-morrow at the Harveian Society on "The Diagnosis and Treatment of Fractures in the Neighbourhood of a Joint."

MR. CHARLES JAMES OLDHAM, F.R.C.S., of Hove the well-known ophthalmic surgeon, who died on January 24th, left about £50,000 for educational purposes, and several Strad violins to the British Museum. His estate is valued at £77,959.

DR. G. B. MASON, Medical Officer of Nevis, West Indies, has been promoted Medical Officer and Magistrate of the Windward District of the Island of Dominica

NURSE SARAH CROSS has been presented with an illuminated testimonial by the Board of the Middlesex Hospital, in recognition of her devotion to the sufferers from the Jamaica disaster.

THE annual court of governors of Middlesex Hospital last week was presided over by Mr. Henry Morris, in the absence of Prince Francis of Teck.

AT the London County Council Election, on March 2nd, we notice amongst the successful candidates the names of Dr. R. M. Beaton, Dr. J. Davies, Dr. A. Salter, and Dr. P. Vosper; amongst those defeated were Drs. Davidson and Fletcher Little.

AT the Royal Commission on Vivisection held on February 26th and 27th, Viscount Selby presiding, Mr. A. R. Cushny, Professor of Pharmacology and Materia Medica in University College, London, and Miss A. Kenealy, from the Parliamentary Association for the Abolition of Vivisection, gave evidence.

MR. J. B. CHRISTOPHERSON, M.A., M.D. (Cantab), the Senior Medical Inspector of the Sudan Government, has been appointed Director of the Sudan Medical Department, to date from the 1st of January.

THE Holywell Rural Council have re-appointed Dr. Jas. Williams, of Castle-hill, Holywell, as medical officer of health for the Holywell district. He has been termed the "Grand Old Man of North Wales medical officers," having held the office over half a century.

A CLINICAL LECTURE

ON

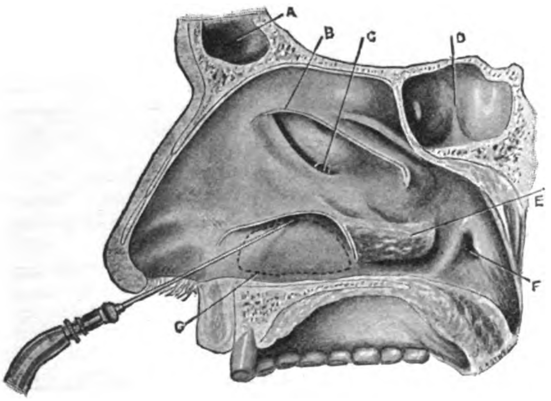
EMPYEMA OF THE MAXILLARY ANTRUM. (*a*)

By PATRICK DEMPSEY, F.R.C.S.I., M.R.C.S.Eng.,

Surgeon for Diseases of the Throat, Nose, and Ear, Mater Misericordiæ Hospital, Dublin.

Suppuration of the accussory cavities of the nose has within recent years justly claimed much attention. Badly drained, and easily overlocked, these purulent collections may easily cause not only much local trouble, but also symptoms of a very remote nature. I intend to-day to concern myself entirely with the maxillary antrum and I may preface my remarks by saying that it is quite impossible within the confines of this lecture to treat the subject exhaustively. The surgery of any region is intimately bound up with its anatomical relations and to the antrum this rule applies with emphasis. Without going into unnecessary details, let me therefore remind you that it is a hollow space roughly triangular in shape and situated in the sup. maxilla, the orbital place of which forms its roof, and the alveolar process the floor. The outer wall of the nose is its base, while the facial and zigomatic surfaces are responsible for the outer wall of the cavity. A glance at this recent specimen in which the antrum has been laid open will give you a clear idea of the relations.

Lateral Wall of Nose.



A.—Frontal Sinus. B.—Edge of Cut Middle Turbinal. C.—Opening of Maxillary Antrum. D.—Sphenoidal Sinus. E.—Inf. Turbinal, Anterior Half of which has been removed. F.—Eustachion Tube. G.—Dotted Line corresponding to Portion of Antro-Meatal Wall removed in Radical Operation. Needle in position for Experimental Puncture.

The middle turbinal has been removed (Fig. 1, B), in order that a good view of the hiatus semilunaris may be had. At the posterior portion of this latter you can see the normal opening of the antrum (Fig. 1, C), and I should like you to note how high this is situated with relation to the cavity which it must drain in the event of suppuration. Observe closely, also, the floor from inside. In this particular specimen the roots of the second bicuspid and first molar are separated from the cavity by a considerable thickness of bone, but in many cases they actually project so far into the antrum as to be quite visible when this latter is opened. It must strike the most casual observer, therefore, that the anatomical conditions most likely to be of clinical interest are those depending on the proximity of the nasal fossæ and teeth. And so it largely is in practice. The view formerly held that diseased teeth were practically the only cause of suppuration has of later years been disproved. Grünwald (*a*) out of 98 cases could only trace the disease directly to the teeth in 14, but in my experience the average is higher. I have notes of 33 cases, and in 12 of these a bad tooth was the unmistakable cause. Most common of all histories given by patients is " severe cold in the head, followed by a nasty nasal discharge." Whether the " cold " has been a genuine attack of influenza or an acute rhinitis is not always easy to find out at the time when the case comes under observation, but there can be no question, as maintained by Hajek (*b*), that the influenzal bacillus is a common cause. Such a good authority as Killian believes that a great number of cases are due to attacks of simple rhinitis and most observers agree with this view. There are many other points in the ætiology, but I shall only mention that erysipelas of the face, typhoid, and other infectious fevers are occasionally met with as predisposing agents.

The next point to be considered is, what are the most characteristic signs and symptoms of suppuration in the maxillary antrum? By far the greater number of my patients sum up their complaint with the words " constant cold in the head," and I must warn you to be always on the look-out for sinus disease when you listen to a similar statement. Question as to *whether the " cold " is unilateral*, and find out if the patient has at any time noticed an offensive odour, for this latter is frequently present. That offensive odour is perceived is not remarkable if you bear in mind the fact to which I have already drawn your attention, viz., the height of the normal maxillary ostium. So close to the roof of the latter is it that unless the head be tilted or lowered the contents must of necessity be to a certain extent stagnant, and thus an easy prey to putrefactive charges. This anatomical fact will also account for the *gushing or periodic character of the discharge* often complained of and due to the relative lowering of the opening as a result of changes in the head's position. Headache is a fairly common symptom, sometimes of a boring nature, sometimes neuralgic. In some of my worst cases it has been entirely absent, but at the same time it is astonishing the number of patients who have for years been martyrs to headaches directly due to suppuration of one or more sinuses, and who have been treated with all the analgesics in the Pharmacopœia, change of air, electricity, etc., and who have never suspected or had it suggested that the cause might possibly be nasal. Hajek draws attention to the fact, and I have noticed it also myself, that sufferers from chronic suppuration of the accessory cavities are particularly sensitive to even the mildest forms of dissipation. Smoking, even in moderation, or a very small quantity of alcohol may cause headache and depression out of all proportion to the exciting cause. Nasal obstruction due to hypertrophic changes or polypi, interference with smell, bad taste in the mouth, possibly gastric disturbance due to trickling down of pus *via* the pharynx are other symptoms which are often present.

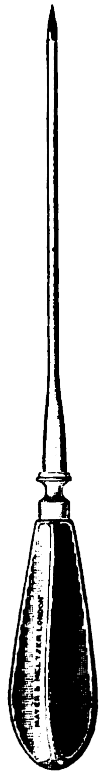
So much for the more important symptoms, all of which may be elicited without intranasal examination.

(*a*) A lecture delivered at the Mater Misericordiæ Hospital, January, 1907.

Let us now suppose that we examine the interior of the nose of a typical case of chronic antral suppuration. The first point in the examination that has frequently struck me is that the side—in unilateral cases—which is affected is the narrower one; that is to say, if any deflection of the septum or spur be present the side on which one or both of these exists is the one more usually diseased.

No pus may be seen in the nose, but as a rule on careful examination a yellow streak is to be observed in the region of the middle meatus and this may be increased in quantity by tilting the head towards the unaffected side so as to lower the natural means of outflow. Even when no pus is seen in the mid-meatus, this particular region always appears to me to wear a somewhat characteristic look. The ant. end of the mid-turbinal is nearly always hypertrophic in varying degrees, the meatus has a moist appearance, and is often "mottled" with specks of yellow. A preliminary spraying of a 5 per cent. solution of cocaine is a great aid to clearing up the field, but I always like to get a first impression of parts as they actually are.

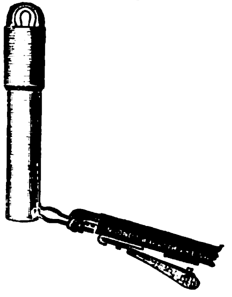
Take it, therefore, that we have some or all of the signs I have mentioned, plus the presence of pus in the mid-meatus which has reappeared after mopping up on lowering the head; how is the diagnosis to be completed? That the antrum certainly contains pus can be proved by washing it out with some clear fluid and noting the character of the latter on return. This little operation, known as experimental puncture of the antrum, is performed as follows:—A small pledget of wool soaked in a 20 per cent. sol. of cocaine is pushed in between the ant. end of the inf. turbinal and the lateral wall of the nose.



Complete local anæsthesia will be produced in about three minutes. Having removed the wool, take a stout hollow needle, such as the one I show you, known as Lichtwitz's, pass it backwards and upwards between the inf. turbinal and the lateral wall of the nose for a distance of about one inch, and then push sharply through in an outward direction (see Fig. 1, in which ant. ½ inf. turbinal has been removed). Failure to puncture nearly always arises from not getting the point of the needle sufficiently high up; it should be right under the attachment of the turbinal, in which region the bone is quite thin. The antrum may be also punctured through the middle meatus, but there is always a slight risk of entering the orbit, which in some cases indeed descends so low as to make this accident unavoidable. The needle having entered the cavity, some clear bland antiseptic fluid is syringed through it and its character observed as it issues from the nose. Pus, if present, cannot escape observation.

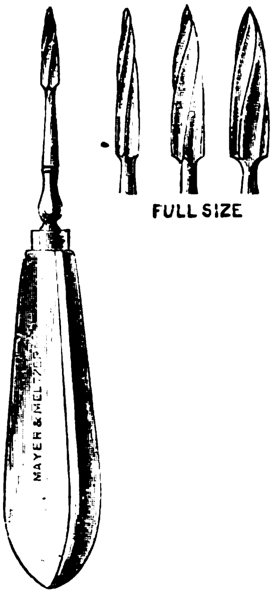
Next in diagnostic merit is that known as "transillumination." It consists essentially in introducing a bright light into the mouth in a dark room, closing the mouth and noting the effect on the face of the passage of the rays of light through the facial bones. Dental plates must, of course, be first removed.

This experiment is easily carried out by means of such an apparatus as the one I show you. The lamp is an 8-volt one and may be switched on after introduction into the mouth by pressure on the small lever which is present on the handle. The current may be taken from main or accumulator. In a normal case, and provided that the bones are not too thick, the inducing of the current is followed by (1) a bright glow over the cheek; (2) above this, but separated by a dark patch, *a bright crescent*, the "infraorbital crescent of Heryng"; (3) a red glow in the pupils; and (4) a subjective sensation of light experienced by the patient (Brown Kelly). In suppuration of the antrum, Nos. 2, 3, and 4 are absent. *The* important phenomenon, and the one to which I pay most attention, is the absence of the infra orbital crescent. With very rare exceptions, I have always found this sign absent in disease, and I look upon it as very reliable. At the same time, I have never yet operated on an antrum without having first performed an "exploratory puncture."

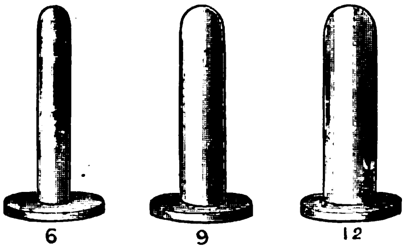


The simplest possible form of treatment consists in removing, if necessary, the second bicuspid or first molar tooth, drilling up into the antrum, through the alveolar process, introducing a plug which remains *in situ* and which may be removed by the patient to perform daily lavage by means of a cannula attached to some such arrangement as a Higginson syringe. I employ vulcanite or rubber plugs. The choice of tooth will be influenced by the presence of disease; other things being equal, I make my opening through that part of the alveolar corresponding to the root of the first molar.

This little operation is satisfactory for acute cases, but when the disease has been present for a lengthened period it rarely does more than relieve troublesome symptoms, and then only when lavage is carried out with great regularity.



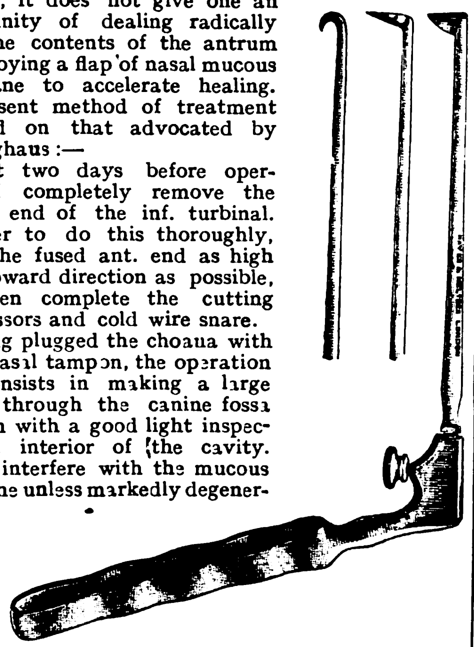
As a more radical method of treatment, Küster some years ago advised that the antrum should be approached through the canine fossa. A large opening could be made in this region, the antrum inspected, diseased mucous membrane or polypi removed, and the cavity then treated by daily packing with gauze. Subsequently, when the wound has become small, a vulcanite plug might be fitted through which lavage could be carried out until all discharge has ceased. This operation has given poor results in my hands and may be now disregarded. All the more modern methods of treatment aim at establishing a free communication between the antrum and the nose. This method of operation may be carried out from the nose and is strongly advocated by Lack. Removal of the ant. half of the inf. turbinal is absolutely necessary in order to obtain a view of the inf. meatus (Fig. 1), through which the communication is made, and various forms of cutting knives and punches have been devised to



facilitate the operator. This method has its advantages but apart from the difficulty of making a wide opening, it does not give one an opportunity of dealing radically with the contents of the antrum or employing a flap of nasal mucous membrane to accelerate healing. My present method of treatment is based on that advocated by Bonninghaus:—

About two days before operation I completely remove the anterior end of the inf. turbinal. In order to do this thoroughly, I saw the fused ant. end as high in an upward direction as possible, and then complete the cutting with scissors and cold wire snare.

Having plugged the choana with a post-nasal tampon, the operation itself consists in making a large opening through the canine fossa and then with a good light inspecting the interior of the cavity. I don't interfere with the mucous membrane unless markedly degenerate, but polypi, etc., should be removed. The next step is to make the communication with the nose by freely removing that portion of the antro-meatal wall (see dotted line G, Fig. 1) corresponding to the ant. half of the inf. meatus. In order, however, to accelerate healing, it is advisable to save the mucous membrane of the inf. meatus, so that it may be subsequently used as a partial lining for the antral cavity.



This is a matter of some difficulty and I get over it in the following way. With the index finger shoved well into the inf. meatus so as to act as counter pressure I employ a small trephine from the antrum side. I trephine very cautiously and stop as soon as the instrument is plainly felt by the finger in the nose and then proceed to remove the trephined piece of bone with a fairly sharp thin bent elevator. To do this is not difficult, and then, with the same elevator, the mucous membrane of the entire inf. meatus may be stripped off.

I next proceed with a Grünwald's forceps to nibble away the bone corresponding to the stripped mucous membrane, and having done so form a flap from the latter by means of two vertical and a horizontal incision. The flap is turned down into the antrum, and the original wound over the canine fossa brought together by a couple of catgut sutures.

In the removal of the antro-meatal wall it is of importance to leave as little ridge as possible between the floor of the nose and the antrum, and also to make the opening as far forward as possible to facilitate subsequent treatment through the nose.

It is well to tampon the cavity for a couple of days after the operation in order that the flap may keep in position, and subsequent treatment consists in daily irrigation of the cavity with a bland antiseptic *via* the nose. In my two last cases, having at the preliminary operation removed the portion of inf. turbinal, I stripped the mucous membrane from the inf. meatus and introduced a strip of gauze between it and the antro-meatal wall. This made the subsequent removal of the bone without injury to the mucous membrane very simple, but it is not an easy procedure unless the patient is tolerant. Time does not permit to discuss other forms of operation, but I must just mention, in conclusion, that Kretschmann (*c*) and Denker (*d*) prolong the original incision to the middle line, turn up the soft parts and procure their nasal flap before opening the canine fossa, the difference between the two operations being that Denker is more radical in the removal of bone, taking away, as I understand him, the entire ant. portion of the nasal lateral wall. I believe the method I employ to be equally as efficacious and not so troublesome. In conclusion, let me press home to you the fact that chronic suppuration of the antrum is frequently met with, often overlooked, and a disease which when chronic requires surgical treatment of a radical nature.

NOTE.—*A Clinical Lecture by a well-known teacher appears in each number of this journal. The lecture for next week will be by E. W. Scott Carmichael, M.B.; F.R.C.S.E., Senior Demonst. of Anatomy School of Medicine; Assistant Surgeon Royal Hospital for Sick Children, Edinburgh, on "Some Pneumococcal Affections requiring Surgical Treatment."*

ORIGINAL PAPERS.

PSYCHORHYTHM AND RECURRENT PSYCHOSES. (a)

By THEO. B. HYSLOP, M.D.,

Senior Physician, Bethlem Hospital; Lecturer on Insanity, St. Mary's Hospital.

PART I.

THE following remarks will be confined to a group or groups of cases characterised by their periodicity or recurrence at fairly constant intervals.

By the term "psychorhythm" I mean the rhythmical recurrence of certain psychic states. There are some mental characteristics which are common to us all. In early life we acquire mental impressions more readily in the mornings, and the later hours of the day are more suitable for the processes of digestion or mental rumination—if I may use the term. As we progress towards senility there is apt to be a curious renewal of the process, *i.e.*, our brains, during the early hours, ruminate upon the earlier acquisitions, and under certain conditions of bodily health it is in the early hours that facts both pleasant and unpleasant are apt to recur. This fact is well known both inside and outside asylums, and in many cases of melancholia, the earlier hours of the day are fraught with the greatest sufferings and dangers. My experience has taught me that the earlier hours of the day are those most to be dreaded by the morbid mind, and this is most characteristic in adult life, especially so when insufficient rest and sleep begins to usher in a neurasthenic state, the result of a life of nervous and mental toil. The later hours of the day are characterised by an apparent increase of the vital functions, with, however, a diminution of the stability of the reflecting powers, a diminution of the controlling faculties, and, consequently, a greater tendency to impulsion. These characteristics of normal life are to be seen in exaggerated form in the sane as well as in the insane. Thus it is that resolutions are made and broken with equal facility, in accordance with the law of periodicity or psychorhythm.

I give merely this one instance of daily rhythm, for to enumerate the results learned from psycho-physical methods of research upon the daily variations of the mental faculties would require several hours.

(*a*) Read before the Harveian Society, February 14th, 1907.

These psychorhythms, however, are not confined merely to daily variations. Most of us are conscious of certain periods of fitness and unfitness, of days of depression and days of gladness. Stable indeed is the man who knows no variation in his mental calibre and moral worth. As Emerson says, "there shall be alternation for evermore," and perfect stability is suggestive of fixity. Charcot's dictum that "immobility is the finest movement of the soldier," is best exemplified in the stuporose and cataleptic, and the only true stability of mind known to me is to be seen in the monoideistic person who knows no emotion. It is the rule rather than the exception, therefore, for all of us to have psychorhythms, and the various types I shall mention are mainly exaggerations of these conditions.

Normal variations occur in relation to our sensory and perceptive powers, our memories, feelings, and actions. These variations are not only normal but symptomatic of mental and physical health.

The seasons and climate have some interesting relationships to mental disturbances which we may note in passing. Parchappe and Esquirol are agreed as to the greater frequency of attacks of insanity, or at least admissions into asylums in the summer months. Guislain observes that there is a relation between the warmth of the atmosphere and mental disturbance. A fall of temperature, on the other hand, often calms the insane. MM. Aubauel and Thore observe, as the result of their investigations, that the month of June appears (in France at least) to have the most influence in producing insanity, then July and August, next May and April, January having the least influence. Periodical or recurrent insanity is especially manifested in the spring. It is a fact, nevertheless, that we do not find more insanity in hot climates than in cold. According to the records of Sydenham, Benedict, and Brierre de Boismont suicides are more frequent in the months of spring and summer. The last-named observer found that of 3,518 cases of suicide committed in France, in which the exact period of the commission of the act was discovered, 2,092 were in the day, 658 in the night, 766 in the evening.

To the alleged influence of the moon I will refer briefly. The operation of the stars, if not the moon, on disease, was recognised by Hippocrates, and that of the moon was certainly admitted by Galen. In connection with the observations that light in itself tends to excite, and darkness to calm many of the insane, Rush concludes that the cases are few in which the insane feel the influence of the moon, and that mere increase of light is sufficient to explain excitement in such cases. Esquirol, Teuret, Mitivié, Woodward, and others have investigated this subject with failure to find any relation between them. They find coincidences and nothing more. "Many patients are certainly more excitable and restless on pleasant moonlight nights than in dark and gloomy weather, but this," says Hopkins, "would seem to be occasioned by the real or imaginary sight of objects in or without the building, such as men, trees, animals, etc., or the motion, perhaps, of the passing clouds. I think we may rightly assume that light stimulates the brain to activity, hence the greater excitement of some patients at the period of the full moon. Moreover, one noisy patient awakens others, hence a general disturbance in the wards of asylums. Coincidence also has to be reckoned with. Thus the menstrual period of the female with recurrence of sleeplessness and excitement, or metabolic phases, such as uric acid crisis in the male, may coincide with the phases of the moon.

I now propose to speak of certain exaggerations of the psychorhythmic process which tend to cross the borderland of sanity. These cases fall into two large groups, and may be described as perversions of mind due to

1. Deprivation of factors pertaining to complete consciousness.
2. Faults in metabolism and toxæmiæ.

The first group comprises a wide range of conditions in some respects comparable to the insanities resulting from deprivation of the special senses. The loss of any of the five special senses by which we keep in touch with our environments necessitates a re-adaptation of the remaining senses with possible over-stimulation of them. The result of hyperactivity of these senses without the corrective action of the missing sense is apt to result in false constructions or delusions. The cases to which I now refer, however, do not result from deprivation of any one special sense, but rather do they depend upon some cerebral condition whereby certain regional acquisitions and modes of mental reaction are periodically and temporarily cut off from the consciousness as a whole. Consciousness when complete, *i.e.*, with full and complete adaptation of the subject to the environment, depends upon perfect anatomico-physiological arrangements. The answer of cerebral anatomy and physiology to the question of the localisation of consciousness has been of little value hitherto, and we are still unable to account for the phenomenon of consciousness by the study of material structures. I do not for a moment pretend to be able to explain the mode by which the subject obtains its view of the objects correlated with cerebral activities in widely-apart localities. Without going so far as Kirchhoff, who believes that all internal processes constitute consciousness, and that there are no individual modes of consciousness, I believe there is evidence that consciousness may exist in conjunction with activities occurring in one or several of the regions of the cerebral cortex, while other regions are synchronously inactive as physical concomitants of mental phenomena. In fact, it seems fair to assume that full knowledge or complete consciousness is dependent upon complete seriality of perception and memory derived from activities within the whole cortex, and possibly incomplete knowledge or partial consciousness may be derived from a disruption of that seriality or sequence through inactivity of part of the cortex. This leads me to the consideration of the phenomena of double consciousness, and the various epileptiform states which would appear to warrant this assumption, and by its aid some of the greatest of the difficulties of these conditions may be unravelled.

Unconsciousness may be *partial* or *complete*. By "*partial*" is meant a suspension of psychical or physical elements which are necessary to a full or complete consciousness. By "*complete*" is meant the seriality of thought and discrimination (or knowledge) which is available by reason of perfect action throughout the cerebral cortex.

Partial loss of consciousness is exemplified in those individuals who, by reason of disorder or disease, suffer from partial amnesia. Ribot compares each particular form of memory with a contingent of clerks charged with a special and exclusive service. Any one of these departments might be abolished without serious detriment to the rest of the work, and that is what happens in these partial disorders of memory. It may be objected that in these partial amnesias there is not immediate loss of consciousness to present facts. The answer is manifest. Any present data which are incapable of being incorporated with the general stream of consciousness, seriality of thought, or knowledge, by reason of some cerebral defect, are outside the limit of "present knowledge," and the reflex, if there be one, is the result of activities within the undamaged remainder, and therefore only incomplete, and oftentimes merely automatic.

At the risk of some repetition, I would further exemplify this contention by comparing the highest evolved centres to a huge congerie of units or groups of units which are functionally continuous under certain conditions of contiguity with the periphery and with each other. These units may be compared to lamps, which give light when their respective electric phenomena are in operation. Provided that the switches and transmitting agents, both peripheral and central, are functionally operative, they light up in turn in response to the stimulus, be it peripheral or central. Carrying this hypothesis further, just as the switches, couplings, or currents may under one series of conditions become functionally inert at one time, leading to inability to produce light in one or several sets of lamps, so under another series of conditions may the same switches, couplings, or currents again become functionally active and determine the existence of light.

It seems justifiable to assume that the recurring amnesic defects which go so far to constitute what we call double-consciousness, are due to failure under one set of conditions to switch on lamps which had previously been alight under another set of conditions, and which may again be lighted under that other set. This hypothesis would appear to demonstrate how it is that there may be no end to the number of personalities in one individual.

Of all the forms of psychorhythms, alternating or recurring psychoses, none exceed in interest these conditions of double, or, more strictly speaking, partial consciousness.

This condition has been compared to dream, somnambulistic, epileptic, amnesic, and insane states, and I have elsewhere cited instances of the various gradations between them and health.

In childhood, night terrors or somnambulism may precede a condition in which during the day time there are moral, or volitional perversions, of which, in the fully awake state there remains no memory or power to recall. These children usually belong to the front of unstable neurotics who may become criminal or insane according to surroundings. In early life their instability is manifested by convulsions during teething. At puberty they suffer from night terrors, various forms of epileptiform automatism, habits of lying, thieving and moral depravities. At adolescence they are apt to become insane or criminal, and of all resultant forms of insanity most to be feared dementia precox is the worst. The children of drunken or neurotic parents are the most liable to suffer in this way, although I have quite recently seen four instances in which the patient has been the last born of a large family, and when the father has been over fifty-five years of age.

The next type is one in which the abnormal state is preceded by profound sleep. In these cases the sleep may be followed by partial awakening attended by confusion and pranks of the senses, and later in the day complete awakening. In other types the automatic states are preceded by profound sleep, and the normal is only reached again after prolonged sleep. Other types which may be mentioned briefly are: Conditions of temporary, periodic or recurrent amnesia due to shock or injury. I have seen several cases in which not only has unconsciousness immediately followed the injury, but at a subsequent period, months or even years later, curious anomalies of consciousness have occurred. These abnormal states may be likened to double consciousness, inasmuch as the patient may for weeks or even months respond to external impressions in a dazed confused manner, and be apparently in a degree conscious. On awakening, however, to full consciousness there is more or less complete failure to recall the details of the partially conscious period.

The epileptiform types of mental disturbance need not detain us, as they are already so well recognised.

The condition of double personality, however, is not so well recognised. There are several main groups. In *complete* alteration, the personality of the individual is entirely different in the two states; there is no continuity of thought, and the memory of one state is absent during the occurrence of the other. In the *partial* types the variations may depend upon sensory experiences which are different to those habitual to the normal self, and there may be new bodily sansations, or loss of old ones, and there may be illusions of identity of part or of the whole of the individual.

The *anæsthetic hysterical types* are those in which the symptoms are mainly hysterical with anæsthesia and temporary amnesia. In these cases there are certain "inhibitions" which prevent the recall or revival of the former sensations. Thus the occurrence of anæsthesia or a kinæsthesia may be attended by and followed by an amnesia which forms the basis of a change in personality. Another type in which the individual assumes the possession of a mediumship, and acts as if animated by others living or dead, is fairly common. Automatic writing, inspirational speaking, trance utterances, etc., fall into this category.

Before leaving this part of the subject I would refer to the recurrence of mental disturbance mainly attributable to expectant attention. The occurrence of one or more attacks at a certain season, or in association with certain states, such as the puerperal, is apt to lead the individual to anticipate a recurrence, and this in no small measure favours the onset of the mental trouble. With regard to puerperal insanity, it is well known that recurrence of the malady may sometimes be avoided by the avoidance of pregnancy for four or five years.

(To be continued.)

THE POOR-LAW MEDICAL SERVICE IN IRELAND. (a)

By THOMAS DONNELLY, M.D., M.A.O.,
Univ. Dublin,
Fellow and Member of Council, R.C.S.I., D.P.H.

To the Poor-law system in Ireland a renewed interest has been given by the recently-published Report of the Viceregal Commission. It is quite remarkable the unanimity with which this Report has been praised—a compliment which rarely falls to the lot of such documents; and I select that part of it for discussion which deals with the State Medical Service for Ireland, simply because it is the only part which is to any extent open to criticism.

The Poor Law Medical Service forms so large a part, and is so important a factor in the medical life of Ireland, that anything which affects it affects the entire medical profession in Ireland. It is not too much to say that only through this service can the profession in Ireland ever hope to take a full and active part in the national life of the country; only through it may we hope to secure for the profession a place in the social and political world commensurate with its public utility.

The dispensary doctor used to be the *Pooh-Bah* of his district, without, however, those comfortable emoluments which enabled the gentleman of Gilbertian fame to accept with resignation his multifarious duties.

I start with the incontrovertible proposition that the Poor Law System cannot remain as it is. No doubt, as some may say, it will be a long time before any of the reforms suggested in the report are put into effect; but, nevertheless, I hold firm to the opinion that once a system is found to be—as this one is—out of joint with the times, that then the period of its extinction is not far distant. I assume, as I believe I am justified in assuming, that should any change be made in the constitution of the present poor law system in Ireland, the dispensary medical service, as well as the workhouse and county infirmary services, must of necessity be included in the readjustment. It would not be possible to rearrange the management of the sick poor to any advantage without at the same time altering to a certain extent the construction of the different medical staffs that attend upon them. I would deprecate, however, most strongly, any attempt to amalgamate the coastguards, police, Irish lights, etc., services, with the Poor-law medical service. These services are perfectly distinct and separate, and have a character and objective quite different from the Poor-law Service.

The position of affairs in this year of grace 1907 is this: the State suggests the formation of a State medical service. The representatives of the people do not want a State medical service. The medical profession may be said to be fairly divided in opinion. They are, and have been for many years, extremely discontented with the conditions prevailing in the service with respect to pay, pension, promotion and position. I would suggest that the medical profession should try to bring about some compromise between the present arrangement and the proposed one—admitting on the one hand that the State must have, in lieu of finances supplied, a voice in the disposal of the money, in the fixing of the standard, in the arranging of the work; and that popular representatives should have, on other hand, the final election of the man who is to be the people's doctor and live amongst them, and have at least as much control over his actions as they have at present.

(a) Being an abstract of a Paper read before the State Medicine Section of the Academy of Medicine, on Friday, February 8th, 1907.

The county hospital scheme, with smaller district hospitals affiliated, advocated by the Commissioners, appears to have met with general approval, and in formulating some such alternative scheme as I have mentioned, I will take this as a basis. I assume the abolition of workhouses as such, and their conversion to other specific purposes. I take it that no time or money would be expended in opposing the establishment of these county hospitals, especially if buildings already in existence were used, and I also assume that the necessity for having district hospitals would be readily admitted. By no other means would the poor in outlying districts be so effectively reached and treated. I do not know what the Commissioners meant by "district hospitals." To my mind the residence of each dispensary doctor would need to be one. Having established the county hospital in the most central town of the county, it would then be advisable to map out afresh the dispensary districts, many of which are at present unnecessarily inconvenient, both in size and shape. This would not mean the undue multiplication of districts; quite the reverse. In the centre of each district the dispensary doctor's residence should be placed, and would, of course, belong to the office, and be free of rent, and attached thereto all that would be necessary to constitute an emergency hospital. There would be, say, four rooms, arranged in wards, a pharmacy, with all drugs and apparatus suitable for urgent cases, as well as the ordinary ailments, which two classes of case would be, it is contemplated, alone treated there. Attached, also, should be a residence for a district nurse, who should have a midwifery diploma. As the districts would be more conveniently arranged, fewer outlying dispensary depots would be necessary, but wherever required they should be established and attended by the medical officer. By these means, and also by the establishment of a complete and extensive system of telephonic communication, which will, no doubt, take place in the near future, the doctor would be quite in touch, and capable of dealing with any case that might arise, and the poor could feel that they were within reasonable reach of medical assistance. The county hospitals should have at least two resident medical officers, and also an out-patient department. This would obviate the necessity for having dispensaries in the immediate neighbourhood of the hospitals, for there is no reason why the hospital medical officers should not visit at the houses of the sick poor, within a certain distance of the hospital. The county hospital surgeons would be, in fact, the dispensary doctors for the area around the hospital. It would be desirable to have one of these medical officers an operating surgeon, one a physician, and in places where there are three residents, one a gynæcologist. There should be no difference in rank or remuneration between the county hospital medical officers and the dispensary or district hospital medical officers, except those which fortuitous circumstances might give rise to; but lest these should amount in practice to something considerable, it should be the rule that positions falling vacant should be filled from the ranks of the service before new appointments be made.

To insure that the dispensary, or, as they would be called, district hospital surgeons, would have the requisite experience—besides the cases treated in his own small hospital, the district hospital surgeon should have the right of assisting at operations, and visiting in consultation with the resident all patients from his district in the county hospital.

The above is a sketch of a very simple mechanism, but one which from my experience as a country dispensary doctor could be made a very effective and comprehensive one. The salaries of all the medical officers would be the same, say £200 per annum, rising to £400, together with registration and vaccination fees, etc., and residence free of rent and taxes. All this should be paid by the State. An annual holiday of one month should be granted to each medical officer as a right, free of expense. Every medical officer in the service should be permitted to retire on half-pay after 20 years' service, and should be compelled to resign at 65 years of age on two-thirds of his salary and emoluments. This would bring about a healthy circulation in the service, good alike for the poor and the profession, and has been found beneficial in nearly every other service. The grave objection to the Commissioners' report, and one which would be fatal to its adoption, is the constitution of the council, or board of control, which, according to them, would be necessary. I foresee that endless disputes would arise on this point, and that—apart from the objection to having any more boards added to the 42 already in existence in Ireland—it would be hopeless ever to construct a board that would please everyone. This would tend towards what I most dread—namely, the indefinite postponement of the settlement of this vital question. Let us see if we could not dispense with another board altogether. Let the State, or the Local Government Board, have inspectors, as at present, increased in number if necessary, to make sure that the system is properly carried out, to prevent abuses creeping in, and to hold inquiries when called for. Let the management of each county hospital and its affiliated district or dispensary hospitals be in the hands of a large and representative committee. The committee of management might be elected at their first meeting by the county council, and could be made up of, say, one councillor from each district, the county medical officer of health (of whom more anon), one representative of the government, and two clergymen—one from each of the two prevailing denominations of the place. Of course I only throw out this suggestion for discussion. In the hands of this committee would rest the election to all medical posts in the county, though, of course, subjected to the formal sanction of the Local Government Board. In order to guarantee a high level of efficiency, which is really all that the State should require, let only those who, being fully qualified in medicine, surgery, and midwifery, and registered, have, in addition, an extra certificate in the practice of obstetrics, a certificate in lunacy, and at least twelve months' experience (not necessarily continuous) as *locum tenens* in dispensary districts, or in lieu thereof, one year's experience in a large hospital, be eligible for appointment in this service, and none others. By this method not alone would good men be procured, but only those who have served, so to speak, an apprenticeship would be admitted into the service. This I consider of paramount importance. If desired, a post-graduate course might be made a condition of promotion or increase of salary, so as to maintain a high level of proficiency. There can be little doubt that the people would not object to a State service on these lines. The State meaning in this connection that the funds necessary are provided by general, not local taxation.

I would suggest, both on the score of equity and expediency, that the county and district hospital medical officers—*all* of whom on my plan would have dispensary duties to perform—should (in addition to the fixed salary and emoluments paid by the State for the definite work of treating the sick poor in the hospitals and dispensaries) be paid by the local authorities a small fee on each red ticket or case visited at the patient's home. I do so for the following reasons:

It is but fair that a man should be paid in proportion for extra work done. At present if a disease becomes epidemic the medical officer is put to great expense for extra car-hire. He is bound to attend dispensary patients first, and if these are numerous, most of his time is used up, to the great detriment of his private practice. Again, the better a man does his work, and the more confidence consequently the poor people have in him, the more calls he gets—all without further remuneration, or even recognition. It would be a check on the improper issue of tickets, and a guarantee that only those entitled to it would receive medical relief, as is the case at present with regard to outdoor relief.

It would also induce the county councillors to take a direct interest in the proper distribution of medical aid to the sick poor, and would be an index to the efficiency of the work performed. It would assuredly prevent the degrading effect of the present system on the minds of the poor people, and they would value more highly medical assistance they knew would be directly paid for. It would enable the medical officer to obtain payment from those well able to pay who now receive medical advice at his expense.

This plan, while just, is no more liable to abuse than the present method of administering outdoor relief, and could be safeguarded in a similar manner. I mentioned just now a county medical officer of health. As we are all aware, the Public Health Department in this country is a farce, and certainly stands in need of extensive reformation. In the first place, dispensary and hospital medical officers should neither be asked nor allowed to do public health work. When it is fully realised what the work of a medical officer of health *should* be, it will be seen that it would be quite incompatible with his duties as a dispensary or general practitioner, which necessarily bring him into private and confidential relations with his patients. No man living by the practice of medicine, and having a *clientele* with whom he must be on good terms, could possibly do public health work efficiently or thoroughly. Men who enter the ideal public health service, which we may hope to see established some day, will be expected to devote their whole time to this class of work, and will be paid salaries sufficient to render them independent of any other source of income. Special qualifications, such as a D.P.H., are necessary, and will be, no doubt, required of them; but then their reports will be received with the respect due to them, and executive power will, of course, be granted to them. Each county should have at least one medical officer of health, and he should be responsible to the State, and do nothing else but direct and see that the various works and regulations for the maintenance and improvement of the public health are satisfactorily carried out. This medical officer of health should have as many sub-sanitary officers under him as would be necessary, and he would be a suitable person to have on the public boards and committees, his opinion on medical matters being a valuable one, while his position would be an independent one. Detailed reference to the public health service is, however, at present outside my scope, and I merely allude to it here to show that I am very much opposed to having the duties of attending to the sick and doing sanitary work combined and performed by the same person.

THE War Office intimates that a number of Queen's South Africa medals and clasps for ex-members of the Royal Army Medical Corps, Royal Army Medical Corps (Militia), Cape Medical Staff Corps, Medical Staff, Rhodesian Field Force and Natives (attached to Medical Units) still await claimants. Applications for these decorations should be addressed to the Secretary, War Office, accompanied by discharge certificates and full particulars of service with other corps.

CLINICAL RECORDS.

A CASE OF FATAL EXTRAVASATION OF URINE FROM THE URETER CAUSED BY THE ULCERATION DUE TO A MINUTE CALCULUS. (a)

By RAYMOND JOHNSON, F.R.C.S.,
Surgeon, University College Hospital, London.

THE case was that of a man, æt. 35, who had recently undergone an operation for an irreducible omental hernia in the right inguinal canal. The operation was in no respect unusual, and a considerable mass of omentum was removed after being ligatured in sections with fine silk. The wound pursued a normal course, and the patient's convalescence was uninterrupted until the thirtieth day, when, after a light meal, a violent attack of vomiting occurred, and severe pain was experienced across the lower part of the abdomen. The vomiting only recurred once on the following day, but considerable pain persisted and gradually became limited to the left iliac region. When seen on the sixth day after the onset of the abdominal pain the patient looked pale and ill; the pulse was 88 and of good quality; temperature slightly raised; tongue moist, but coated. The abdomen presented slight general fulness, especially above the outer half of Poupart's ligament on the left side; in this region there was marked tenderness, which extended somewhat backwards towards the loin. No other facts of importance could be elicited by abdominal or rectal examination, and the site of the operation for the hernia on the right side presented nothing abnormal.

From the evidence it was concluded that the patient was suffering from a localised peritonitis in the left iliac region, but no satisfactory explanation was forthcoming. In spite of the localisation of the symptoms to the left side the possibility of appendicitis was entertained. It was not thought that suppuration had occurred. The patient was put on a strict spoon diet and belladonna fomentations were applied to the abdomen. Two days later the local signs had become somewhat more pronounced, and there was slight dulness above the outer part of Poupart's ligament. The presence of pus was suspected, and operation was performed. An oblique incision was made over the area of dulness, and after dividing the muscles of the abdominal wall the œdematous transversalis fascia was exposed. On dividing this a cavity containing thin pus with a powerful ammoniacal urinary odour was reached. It was uncertain whether this cavity was behind or in the peritoneum, and exploration with the finger merely showed that it extended a short distance upwards and downwards. A large drainage tube was inserted. It thus seemed evident that an infection of the peritoneum or retro-peritoneal tissue had occurred from the bladder or left ureter, but the cause was not known. The urine contained a very faint cloud of albumin, but was otherwise normal. Retention of urine during the first day or two after the operation for hernia a month previously had necessitated the use of a catheter, but there had been no signs of cystitis. It was further learned, as possibly having a bearing on the case, that some months previously, when away on a holiday, the patient had experienced an attack of not very severe pain in the back, which, however, only lasted one day.

On the day after the abscess was opened violent hæmorrhage occurred from the wound, during an action of the bowels, and the patient was *in extremis*. On removing the dressings it was found that the bleeding had stopped, and the patient rallied after an intravenous saline infusion. No further hæmorrhage occurred, but the patient's feeble condition prevented any attempt at further exploration. Small quantities of pus and urine continued to escape from the drainage tube, the temperature remained irregular, and death occurred on the fourth day.

(a) Read at a meeting of the Harveian Society, Feb. 14, 1907.

At the autopsy it was found that the abscess cavity extended in the retro-peritoneal tissue along the whole length of the left ureter from the kidney to the bladder. Lying in the abscess cavity was a small oval crystalline calculus, which proved to be composed of oxalate of calcium, and weighed eight grains. The left ureter at a point two inches below the renal pelvis presented an ulcerated opening at the seat of a slight dilatation. The urinary organs were otherwise normal, and no other stone was found. There was no peritonitis.

The difficulty of diagnosis in this case has been sufficiently indicated, and before the operation the true nature of the local inflammatory condition was not even suspected. It was, indeed, regarded as a local peritonitis, probably due to an infection from the appendix or large intestine.

The hæmorrhage was doubtless due to the sloughy state of the tissues around the abscess, but its exact source was not discovered.

If the condition of the patient had permitted further interference the right treatment would probably have consisted in freely enlarging the incision upwards and backwards, and, after discovering the state of the ureter, removing the kidney.

The case is a striking illustration of the fact that even a very small renal calculus, productive of few, if any, definite symptoms, cannot be regarded as a source of no danger.

OPERATING THEATRES.

ST. THOMAS'S HOSPITAL.

OPERATION FOR IRREDUCIBLE HERNIA WHICH PROVED TO BE OF CONGENITAL ORIGIN, AND RADICAL CURE.—Mr. H. BETHAM ROBINSON operated on a man, æt. 39, who had been admitted for irreducible inguinal hernia. The man gave the following history :—For six months he had noticed a hernia on the right side which had been easily reducible till one week before; since then it had become very swollen, and he had not been able to get it back. There was some tenderness on pressure over the line of the inguinal canal, but there was no marked pain ; there was no obstruction of the bowels. On examination, in the front of the right half of the scrotum was a cystic swelling extending upwards above the level of the external ring, but placed a little outside it. This upper end was definitely pointed. This swelling was translucent, and had impulse on coughing. Along the line of the inguinal canal was a hard cord-like thickening, which after coming through the external ring was placed behind the former fluid swelling, and traced down in the scrotum, extending half-way down the former swelling, and ending in a definite knob-like projection. In this, again, there was impulse on coughing. The testicle was not able to be defined. Before operation the nature of this scrotal swelling was not clear. The history suggested the possibility of the fluid part being a hydrocele of a hernial sac, but the want of recognition of the testicle made this diagnosis uncertain. An incision was made over the front fluid swelling and ordinary clear hydrocele fluid was let out. It was then found that this sac was, so to speak, a diverticulum from the posterior swelling, and had a blind upper end placed outside, and a little below the external ring as made out before. The posterior cord-like swelling was now better defined at its exit from the external ring. The front wall of the canal was freely exposed by dividing the internal and external Obliques, and a hernial sac was exposed with the elements of the spermatic cord spread out all round it. On opening up the sac it was found to be filled with matted omentum, which, passing down in the posterior sac in the scrotum, surrounded a small testicle. The anterior cystic swelling was then shown to have communicated with the posterior one by means of an opening placed in front of the lower part of the latter. The matted omentum was separated, tied off in the inguinal canal and the stump returned into the abdomen. The wall of the anterior sac, which was shown to be a diverticulum from the real hernial sac, was cut away and the real hernial sac behind was also divided above the testis. The large opening thus made above the testicle was closed by a purse string suture, and by this means a tunica vaginalis was made. The real hernial sac was then separated from the constituents of the cord as far up as the internal ring; at this site its neck was transfixed with a silk ligature which was tied round the neck and the redundant sac cut away. The inguinal canal was then closed with silk, Bassini's method being adopted. On completion of the operation it was noticed that the right half of the scrotum proper appeared to be ill developed, and that the testis occupied a site rather outside the scrotum, *i.e.*, the cruro-scrotal position. Mr. Robinson said that the operation thus proved what was the nature of the hernia and how very unreliable the history had been. The hernia was of the form called " congenital hernia," that is, the whole length of the processus vaginalis testis had remained unclosed, so that the abdominal structures which had descended were in direct apposition with the testicle. As so frequently occurs in these cases the development of the testis itself was defective and its descent incomplete. A feature of the case was the diverticulum in front from the sac containing the testis filled with fluid diagnosed previously as a hydrocele. The non-recognition of the testicle before the operation was owing to its reduced size and to its being covered up by the matted omentum. Such diverticula he thought were rare, and no special view could be advanced to explain their production. The important points of the case, he considered, were :—(1) That although the man had a true congenital hernia, he, at the age of 39, only gave a history of six months presence of the hernial swelling ; (2) the nature of this congenital sac with the anterior diverticulum, and (3) the probable descent of the testis out of its proper course.

The patient made an uneventful recovery, and left the hospital about three weeks after the operation.

ROYAL SOUTHERN HOSPITAL, LIVERPOOL.

EXCISION OF HALF THE TONGUE, PRELIMINARY LIGATURE OF THE LINGUAL ARTERY— SECONDARY HÆMORRHAGE—RECOVERY.—Mr. NEWBOLT operated upon a man, æt. 49, who was suffering from an epithelioma involving the right half of the tongue. The growth had existed for three months, and was caused by an injury from a broken tooth. The glands below the jaw on the same side were involved. The latter were dissected out and at the same time the right lingual artery was ligatured. The right half of the tongue was next removed through the mouth, and as the growth extended back towards the root a wide excision was done and parts of the tonsil and fauces were taken away. A vessel in the pillar of the fauces was secured and also the cut lingual, but the operation was practically bloodless. All went well until the fifth day afterwards, when at 5 a.m. the patient began to bleed freely from the mouth. Mr. Newbolt saw him at 6 a.m., and as it was impossible to see where the bleeding came from, the patient was removed to the theatre, the wound in the neck rapidly opened, and the external carotid tied. The bleeding at once ceased and the patient made a good recovery. The bleeding, Mr. Newbolt remarked, apparently came from the fauces, probably from a wounded ascending pharyngeal or one of its branches. In this case, he said, the lingual has been tied as the neck had to be opened up in order to remove the glands, the patient having expressed the wish that the whole operation should be done at one sitting. It rendered the removal of the tongue practically a bloodless operation. No doubt the hæmorrhage came from another vessel, either the ascending pharyngeal, its branches, or possibly the ascending palatine branches of the facial; its late onset was rather remarkable, inasmuch as the wound was sweet and no sloughs were present. Microscopically the growth was a typical squamous celled epithelioma; the glands, however, showed no cancerous deposit. The operation proved to be a highly successful one, the patient remaining well up to the present time, nearly five years having elapsed. Mr. Newbolt considered that the preliminary laryngotomy with removal of the tongue, followed by the removal of the glands later on, as advocated by Mr. Butlin, was undoubtedly the best practice. When, however, the patient wished the operation done at one sitting the ligature of the lingual avoided the necessity for the laryngotomy, as in the majority of cases the wound in the mouth was a dry one and the surgeon could see what he was doing, a matter of necessity in this class of case. Of course, there were exceptions to this rule.

TRANSACTIONS OF SOCIETIES.

HARVEIAN SOCIETY OF LONDON.

Ordinary Meeting, Thursday, Feb. 14th, 1907.

The President, Dr. Sidney Phillips, in the Chair.

Mr. Raymond Johnson, F.R.C.S., read the notes of a case of

FATAL EXTRAVASATION OF URINE FROM THE URETER CAUSED BY THE ULCERATION DUE TO A MINUTE CALCULUS.

(which will be found fully reported on p. 256).

Mr. Campbell Williams remarked on the unique character of the case, particularly the spot in the ureter at which the calculus had become impacted, stenosis at the site being practically non-existent. He pointed out that in the urethra an impacted oxalate of lime stone produced more distress than either a phosphatic or uric acid calculus. The remark was equally applicable to renal colic, the passage of the oxalate calculus causing more distress, even when very small, than other varieties.

Mr. Crisp English spoke of the effect of the shape of the calculus: the small pointed stones are more dangerous than larger rounded ones.

Dr. T. B. Hyslop read a paper on

"PSYCHORHYTHM AND RECURRENT PYSCHOSES"

(which will be found fully reported on page 252 of the present issue).

Mr. Campbell Williams said he was interested to hear Dr. Hyslop's remarks upon the effect of hot weather in the production of mania. He had noted on every voyage which he had taken to Australia that the somewhat abrupt variation of temperature in mail steamers, *i.e*, from cold to heat, was invariably signalised by some unfortunate neurotic, who had been sent a voyage for the benefit of his nervous system, becoming acutely maniacal as soon as the tropical heat affected him. As regards the statement that the curing of either eczema or psoriasis had any bearing on a maniacal outbreak he pointed out that it was probably a coincidence and instanced that these two diseases and lichen planus were probably the most common skin diseases met with, and consequently one would therefore expect mania and cure to be quite a common event. That the causation of these diseases was possibly due to the absorption of intestinal toxine was a theory now receiving attention. Lichen planus when cured by salicine or mercury, given internally, pointed to an intestinal origin—not a syphilitic one, as had been deduced, because it yielded to mercurial treatment, for mercury, like iodides, benefits other diseases as well as syphilis.

Dr. Poynton remarked that insanities alternating with other forms of bodily disease were conditions of supreme interest, and alluded to a case of recurrent and obstinate psoriasis, in which where the rash had disappeared the patient became temporarily insane, and recovered again when the rash reappeared. He also alluded to insanity in mumps, and to the curious cases of infantile eczema in which death followed the disappearance of the rash, the symptoms of the fatal illness being cerebral, with or without hyperpyrexia, and the post-mortem lesions negative. He believed and hoped that certain observations that he had made with Dr. Paine and Dr. Gordon Holmes might in the future result in the elucidation of these difficult points. In six cases of fatal chorea, including one of chorea gravidarum, they had found a bacterium in the meningis or brain, which was identical with that found in other rheumatic lesions, and had found in the brain definite, though not gross changes in the nerve cells. If this bacterium eventually proved to be the exciting cause of rheumatic fever, including chorea, as he believed it would, then here was a cerebral infection which caused chorea, and, moreover, sometimes a mental chorea or form of insanity, for undoubtedly some, and especially adult cases of chorea, might be temporarily insane. The nervousness and night terrors of rheumatic children were, when viewed in this way, also of interest.

The President, Dr. John Broadbent, and Dr. Spilsbury spoke, and Dr. Hyslop replied.

ROYAL ACADEMY OF MEDICINE IN IRELAND.

Section of State Medicine.

Meeting held Friday, February 8th, 1907.

The President, F. C. Martley, M.D., F.R.C.P.I., in the Chair.

REPORT OF THE VICEREGAL COMMISSION ON THE POOR LAW.

Dr. Thomas Donnelly read a paper on the above subject, an abstract of which appears under "Originl Papers" on page 254.

REMARKS ON THE POLICY WITH REGARD TO TUBERCULOSIS OUTLINED IN THE REPORT OFTHE VICEREGAL POOR LAW COMMISSION.

Professor McWeeney read a paper on the above subject. He began by referring to the increase of tuberculosis in Ireland, mentioned by the commissioners in par. 102 of their report. Although quite conscious of the gravity of the problem, he was not at all certain that the figures justified any statement stronger than that whilst the mortality from tuberculosis in England was coming down "by leaps and bounds" it was not showing any tendency to decline in Ireland. The explanation was, no doubt, that whereas in Ireland very little was being done, and that sporadically, in England, amongst other factors, the efforts of independent, whole-time county medical officers of health produced results which could not be hoped for under the excessively bad system which in Ireland placed the health officer's interest in direct opposition to his duty. The recommendation of the Commission that the disused workhouses should be converted into consumption sanatoria deserved their hearty approval, all the more so if Dr. Newsholme's contention be right—that the decrease of the disease in England is mainly due to its increased institutional segregation. The speaker thought it a wise suggestion of the Commission that not only curable but advanced and infective cases should be removed to the contemplated sanatoria. The removal of such from their homes was one of the most essential parts of the campaign, but in Ireland it would be objected to if there were not some prospect of cure held out. By proper classification and rigid observance of regulations he thought that the association in one institution of curable and advanced cases might be rendered unobjectionable. The suggestion of the Commission that consumptive inmates of lunatic asylums should be segregated in a few specially adapted workhouse sanatoria he regarded as particularly valuable, in view of the great difficulty in rendering such cases non-infective. He thought that county councils should have a free hand in devoting public funds to sanatoria, and not be limited to one penny in the pound rate as at present. In conclusion, he looked forward with confidence to the growing-up round the sanatorium of auxiliary institutions such as the dispensary and the volunteer philanthropic committees with the object of providing ex-patients with suitable outdoor or hygienic work, so as to prevent relapse, and sustenance for the wives and families of consumptive working men, so as to secure for them while in the sanatorium that peace of mind which is an indispensable factor in the cure. He pointed out how state invalidity insurance fulfilled this need in Germany, and expressed the hope that workmen's friendly societies would undertake a similar function here. The speaker concluded by saying that the members of the Commission, two of whom he was glad to see present, had by their statesmanlike report earned the hearty thanks of all interested in the struggle against tuberculosis.

Dr. LEONARD KIDD (Enniskillen), said he considered Dr. Donnelly's suggestion that the resident medical officers should do dispensary duty to be impracticable, because if the hospitals were to be levelled up to a high standard it would be a physical impossibility to have high-class surgical work and dispensary work done at the same time. He thought that each large county should have an independant medical officer of health, to whom the dispensary doctors, if they were sub-officers of health, would report. The present method of reporting to the district councils reduced sanitation in the country to a farce. He thought the name "State service" unfortunate, and suggested a "public health and sanitary service." What they ought to have was a board of public health presided over by a minister of Cabinet rank. Although a remnant of the Council of the Irish Medical Association had passed a resolution against the service, they knew that the association was practically unanimous in its favour. The profession was overwhelmingly in favour of some such form of service, and that solely in the interests of the sick poor. The only qualification for admission to hospital should be that of sickness. He was altogether opposed to lines and recommendations from subscribers, especially shopkeepers. There should thereforebe an enquiry officer attached to each hospital. The hospitals should be supported by the county rate, but it would be a pity if the interest of charitable people was killed. Governing bodies might be appointed from members of the county councils and people who lived near the hospitals. Salaries should be fixed to bear some ratio to the work done, and should be proportionately larger in the poorer districts where private practice was small. The clerical work in the country should be reduced to a minimum, and there should be some central body to purchase and test all drugs and apparatus and supply them to the country. He did not consider a single workhouse in Ireland suitable as a sanatorium, from a curative point of view.

Dr. KENNY (Granard) expressed general approval of the report. He did not think the people would have any objection to the profession taking up the control of the State service. They might be inclined to dabble in their affairs, but if the profession showed that their chief concern was to do effective work the public would support them. The profession had pronounced itself very strongly in favour of the recommendations of the committee, not only at public meetings but also in the country, where poor law officers were derelict and without means of communicating with the centres in Dublin. The change to an efficient county service was bound to be beneficial.

Dr. WRIGHT (Dalkey) did not think anyone could doubt that the national medical service would be of great benefit to the sick poor. The carrying out of the recommendations would mean that the younger men would be sent to the outlying districts where they were most needed. Nor could there be any doubt as to its benefits to the profession, since it opened up the possibility of promotion. Boards of guardians would, of course, oppose the recommendations from a natural dislike to have patronage and influence taken from them. The Commission, however, only proposed to take away the election of the medical officers, and he thought any opposition would be got over if it was clearly understood that the State would pay, and that the boards would have full control over their medical officers while holding office. The rates available for sanatoria should be unlimited.

Dr. P. J. GARLAND thought the crusade against consumption should be initiated by a reformation of the public health service in the country. It was controlled, not so much by its officers as by the tenement house and slum owners, whose interests were so jealously looked after by the local bodies that it was impossible for an active and efficient officer to discharge his duties. That department must be taken over entirely by the State.

Mr. M ARDLE said that shortly before the meeting of the Irish Medical Association he objected very strongly to the State medical service under the conditions laid down. Afterwards, when he had learned more about it, he became an enthusiastic supporter of the recommendations of the Commission. The provisions for the benefit of the people generally were so sound that it would be criminal to oppose the scheme for any petty reasons. He did not think there was any need for an alternative scheme. They should confine themselves to broad principles and not to minor details of policy. He thought the question of consumption held a position second to none in importance in those recommendations. If they could not eliminate it they could check it.

Dr. DELAHOYD said the operation of the poor law system had had a demoralising effect on the country, and had destroyed thrift. It would be useless for them to support a State service that would do away with the principle of local control. All entrants should start on equal rights, but there might be certain allowances suited to certain individual conditions.

Mr. W. MICKS and Dr. COEY BIGGER also spoke, and explained some of the recommendations of the Commission that had aroused adverse criticism.

Dr. DONNELLY, in replying, said his paper had justified itself in eliciting such a valuable discussion. If they were to get anything done in a reasonable time there must be some compromise. The trend of popular opinion was against centralisation, and the bulk of the people objected to the service.

Dr. MCWEENEY, in replying, said he agreed that a penny in the pound rate would be insufficient to cope with tuberculosis, but they should see what they could do with that for a beginning. In view of the tremendous mortality from tuberculosis they ought no longer to postpone their efforts, and should not wait for the remodelling of the public health service.

Mr. M'ARDLE proposed the following resolution:—"That the section of State medicine of the Royal Academy of Medicine in Ireland desire to express its approval of the suggestion contained in the Report of the Viceregal Poor Law Commission to convert the entire Poor-law medical service in Ireland into a national service, to be paid by the State, to be entered by a competitive examination, the members of such service to be jointly controlled by the central body and the local bodies, and that the medical profession should have one representative on the central body."

Dr. CRAIG seconded. The resolution was passed.

LIVERPOOL MEDICAL INSTITUTION.

MEETING HELD THURSDAY, FEBRUARY 14TH, 1907.

The President, Mr. FRANK T. PAUL, F.R.C.S., in the Chair.

SUBMUCOUS RESECTION OF THE NASAL SEPTUM.

Dr. W. PERMEWAN read a paper on "Submucous Resection of the Nasal Septum." He described in detail, and illustrated by lantern slides reproduced from Dr. St. Clair Thomson's drawings, the method introduced by Killian, of Freiburg, and then briefly indicated the procedure adopted by Freer, of Chicago. Dr. Permewan insisted on the advantage of operating under cocain, without a general anæsthetic, and said there was practically no pain, no shock and no hæmorrhage. He thought that a satisfactory result could always be predicted, if the operator had sufficient experience and sufficient patience, but the operation should not be undertaken by anyone unskilled in nasal surgery. He then demonstrated the operation on a dissected specimen, and showed the instruments used.

Dr. McDOUGALL thought the submucous operation had a great future before it. He considered it an interesting speculation whether the efforts which had been made in recent years to establish free nose breathing in children would reduce the frequency of intranasal operations in later life.

Mr. T. GUTHRIE could corroborate what Dr. Permewan had said as to the great value of the operation. He asked what Dr. Permewan considered to be the earliest age at which the operation should be performed. Freer regarded it as suitable for all ages, but stated that in children a recurrence of the deformity was probable unless the operation was a very thorough one. Was there any risk that, in children, the operation would involve a subsequent dropping of the bridge of the nose?

Dr. Bark and Mr. T. C. Littler Jones also spoke.

PULSATING EXOPHTHALMOS.

Mr. A. NIMMO WALKER showed a case of pulsating exophthalmos successfully treated by ligature of the common carotid artery.

The patient, a married woman, æt. 29, had been admitted into St. Paul's Eye and Ear Hospital in May, 1906, with the history that six weeks previously she had been struck on the left temple by a large piece of wood, and on the following day had noticed a swishing noise in the head which became gradually worse, with increasing swelling of the left eye. The left eye was found to be proptosed, with dilated episcleral veins, hazy cornea and œdematous conjunctivitis, while the right eye also was congested and prominent; pulsation could be felt in both eyes, and, with the murmur, was controlled by pressure on the left common carotid. The artery was tied, and a month afterwards the eyes were about normal. At the present time, eight months later, the only abnormality was enlargement of the episcleral veins of the left eye, the sight of which had recovered from doubtful perception of light to normal vision with the help of a correcting lens. The vision of the right eye had always been normal.

Mr. WALKER thought that in this case the artery had leaked into the cavernous sinus, but that this, far from being a contra-indication to operation, as had been previously taught, was indicative of its immediate necessity; whether the lesion was aneurysm or aneurysmal varix, early ligature was recognised now as the right treatment, a result largely due to the teaching of his father, Mr. G. E. Walker, who had advocated this operation ever since his first case in 1878.

THE HOUSING OF THE WORKING CLASSES IN LIVERPOOL.

Dr. E. W. HOPE, medical officer of health, gave an account of the position of the city in regard to insanitary property, and the measures taken by the Corporation to deal with it.

He explained the reasons in connection with the rapid growth of the city, which led, during the early part of the century, to its development upon lines resulting in the erection of many thousands of dwellings of an insanitary character. A heavy legacy of insanitation had thus been left for future generations to deal with. In 1883, a special commitee was appointed to deal with the masses of insanitary property existing in the city, and from that year onwards, at varying rates of progress, the work had been proceeded with under the provisions of the Liverpool Sanitary Amendment Act. Dr. Hope explained the difficulties which had to be contended against, and stated that upwards of a million sterling had been spent by the Corporation in removing insanitary dwellings and re-erecting suitable habitations upon their sites.

The compensation for public-house property constituted a heavy item in the outlay. These premises, however, are not spared, as the Council are well alive to the immense injury done by drunkenness in this City.

Apart from the action of the Corporation in removing slums, commercial enterprise had been active; railway companies, warehouse companies, and so forth had swept away large numbers of insanitary dwellings.

In 1883 some 16,000 insanitary dwellings existed. These had now been reduced to between 6,000 and 7,000, and the Corporation had recently decided, pending the sanction of the Local Government Board, to deal with six more areas under the Housing of the Working Classes Act, and to erect suitable dwellings upon them. These schemes were estimated to cost £270,000.

The paper was illustrated by a number of slides showing the old and the new buildings, and the various points in connection with these latter.

Dr. S. H. HOUSE exhibited a number of lantern slides, illustrating the life of the slum children, made from photographs taken in the course of his work as medical officer to the Society for the Prevention of Cruelty to Children.

Dr. G. G. STOPFORD TAYLOR said that the demolition of public-house property would not stem the tide of drunkenness. Education, regular employment and public opinion could alone effect a reformation in the habits of the drunkard, and when these failed his children should be taken from him and brought up at the expense of the State in order to protect them from their vicious surroundings.

Dr. W. CARTER thought that the solution of the slum problem would largely depend upon the solution of the drink problem. Every successive medical officer of health for Liverpool had complained that their efforts at improved sanitation in the houses of the poor were rendered largely nugatory by the prevalence of intoxication. Years ago when the late Professors Parker and Sanderson were invited by the Corporation to inquire into the causes of the insanitary condition of Liverpool they gave a conspicuous place in their report to drunkenness among the working classes. The facts stated by Dr. Hope that £5,000 a year was taken at three public-houses in one of the lowest districts of the city, and that in the whole city from one and a-half to two millions sterling were spent yearly in intoxicating liquors were alarming. It was a good thing for Liverpool that its great public officers were not merely hard routine officials, but had the enthusiasm of humanity to aid them in their great work.

Dr. A. G. Gullan, Dr. Whitford, Dr. J. Hill Abram and Dr. H. Armstrong also spoke.

NOT a single death has occurred for more than a year in the little Devonshire village of Clayhidon, which has a population of 463.

CENTRAL MIDWIVES BOARD.

Meeting held February 28th, 1907.

The President, Dr. Champneys, in the Chair.

Three letters were read by the Secretary to the effect that the Roy. Coll. Phys. had re-elected Dr. Champneys to represent them on the Board for the ensuing year; that the Royal Soc. Apoth. had re-elected Mr. Parker Young to represent them, and a third from the Clerk of the Privy Council transmitting an order to extend the present rules to March 31, 1907.

The question arose of sanctioning Whitechapel Infirmary and Paddington Workhouse as a training school for midwives. Sanction had already been refused on account of structural defects. Mr. Fordham moved that with regard to Whitechapel such refusal be rescinded. This was duly seconded and carried, but the same movement by Mr. Parker Young on behalf of Paddington found no seconder.

Mr. Fordham also moved that "A sub-committee be appointed to consider points of the Midwives' Act which required amendment with a view to laying same before the Privy Council, and a request for their embodiment in a Government Bill during the coming Session." This was duly seconded and carried.

Letters from Dr. Wheatley, Salop, and Dr. Niven, Manchester, requesting information as to the necessity of workhouse nurses holding the Board's certificates received answer that the Privy Council and the Local Government Board were considering the matter.

CORRESPONDENCE.

FROM OUR SPECIAL CORRESPONDENTS ABROAD.

FRANCE.

Paris, March 3rd, 1907.

Hæmorrhage of the Digestive Tract.

Hæmorrhage of the digestive tract is frequent and often grave. A certain number of therapeutic remedies have been tried, but large warm enemas and chloride of calcium would seem to give the best results.

The hæmostatic and antisphlogistic properties of hot water have been known for a long time, yet it was only in the last half of the last century that it was used under the form of injection in the treatment of certain maladies. Trousseau recommended it for metrorrhagia; Eissenmann in nephritis and peritonitis; Emmel in gynæcology in general; Réclus recommends hot enemas in the treatment of uterine affections; R. Tripier in that of gastrorrhagia and dysentery.

As to salts of lime, Green twenty years ago demonstrated that they favoured the coagulation of the blood. A few years later after the experiments of Arthus and Pages, Wright brought to light the action of chloride of calcium, at first in vitro, afterwards in vivo. From his researches he concluded that given in relatively weak doses, chloride of calcium was a good hæmostatic. This conclusion was confirmed by Carnot and more recently by Mathieu, who, little satisfied with the usual remedies employed to arrest the hæmorrhage of typhoid fever patients, tried the association of hot enemas and chloride of calcium. The clinical experiments having been satisfactory, he concluded by treating systematically by this method every case of gastro-intestinal hæmorrhage.

The first thing to be done in case of abundant hæmorrhage from the stomach or intestines, is to enjoin absolute rest in bed and on the back. All nourishment by the mouth is suppressed until the hæmorrhage is somewhat arrested; if it is a manifest case of ulcer of the stomach, nothing but a tablespoonful of water from time to time should be allowed for a few days. But nutritive enemas might be administered if necessary. If the clinical symptoms point to hæmorrhage of the intestine the same *regime* should be followed. If the nutritive enemas are ill supported, or that the general condition is very grave physiological serum might be injected under the skin. To immobilise the abdomen, one can choose between the ice-bag and hot poultices, but to moderate the peristaltic movements of the intestine, nothing is equal to opium given in quarter grain doses at intervals.

If, in spite of all, the hæmorrhage does not cease, M. Dieulafoy recommends surgical interference (?).

M. Mathieu prefers to the usual hæmostatic remedies, hot enemas associated with chloride of calcium.

The cold baths and the milk are suppressed for two or three days and this latter replaced by a certain quantity of water. Morning and evening an enema of boiled water at 118°. To each enema is added one drachm of chloride of zinc, while half a drachm is given in a mixture by the mouth. The quantity of water used for the enema should be at least a quart, and administered very slowly (about a quarter of an hour) by means of an ordinary douche, while a quarter of a grain of opium is given every two hours for four doses.

For hæmatemesis the treatment is much the same, but here it is advisable to have recourse to injections of serum and nutritive enemas to keep up the condition of the patient. The hot enemas are specially useful in removing the clots of blood from the intestine, which otherwise would putrefy and become a source of intoxication and consequent fever.

Sciatica.

A new sign of sciatica has been observed by M. Moutard-Martin—in the case of sciatica of the right leg, for instance. The patient is placed in the dorsal position, low and without a pillow. The left leg is seized and bent gently but progressively on the pelvis, and at a certain moment a sharp pain is felt by the patient in the gluteal region on the right side. To this curious phenomenon he gives the term "counter-lateral," and has observed it in several cases, and would seem to be pathognomic and consequently useful in doubtful cases. Naturally, in order to have the full benefit of the experiments the case should be one of unilateral sciatica.

The Smoking Habit.

Everyone knows how hard it is for a smoker to break off the habit; it is just as difficult for many as to give up the morphia habit. A Russian military surgeon has discovered a very easy, if not very agreeable, means of realising the desire. It consists simply in rinsing out the mouth with a weak solution of nitrate of silver (nitrate of silver 5 grs., water 3 ozs.) After this little operation tobacco smoke produces a most repugnant sensation which effectually destroys all desire for a long time.

Treatment of Appendicitis.

Prof. Robin exposes in succinct language his mode of treating an ordinary case of appendicitis, and which differs in several points from the classical treatment recommended and followed by the majority of practitioners. The patient is in bed, with the ice-bag over the painful region, and all food, even milk, suppressed. only small quantities of water allowed. He begins treatment by a purgative, castor oil or calomel of which two grains are given every hour for four hours. The ice is not applied until the purgative has taken effect, as otherwise it would retard its action. When the patient has been well purged, he examines the condition of the stomach. If it presents signs of hypersthenia he orders an absorbent powder:—

Calcined magnesia, gr. 30.
Bicarb. of soda, grs. 15.
White sugar, grs. 15.
Codeine, gr. 1-10.
Prepared chalk, gr. 12.
S.N. of bismuth, gr. 12.

Each time that the patient any kind of gastric malaise, he is given one of these powders.

Twelve hours after the purgative, he irrigates the intestine with a quart of boiled water cooled down to 100° to which is added two or three tablespoonfuls of olive oil. Before applying the ice, he anoints the flank with—

Strong mercurial ointment, oz. 1.
Belladona extract, dr. 2.

If the patient suffers, he relieves it with

Codeine, gr. ½.
Gentian Extract, grs. 2.

For one pill. Two or three daily.

The patient remains in bed and on the water diet with the ice-bag on the abdomen as long as he feels lancinating pain or tenderness to pressure over the appendix.

When all sensibility has disappeared the patient may begin to take nourishment—milk at first for a fortnight, then farinaceous substances, and finally vegetables, but for months or for years the smallest quantity possible of animal food should be taken.

The consecutive treatment of appendicitis consists in regularising the intestinal function and so avoiding a relapse.

To insure the evacuation of the intestine, Prof. Robin strongly recommends the following:—

Bircarb. of soda, dr. 2.
Sulphate of soda, dr. 1.
Phosphate of soda, dr. 1.
Water, qt. 1.

Of this solution, three ounces are taken (warm) on awakening, four ounces at 11, at 5, and at 9 o'clock in the evening, while large enemas are administered every three days at first and finally once a week, and each time, day or night, the patient experiences more or less gastric disturbance he takes one of the above absorbent powders.

In summer a cure at Châteu Guyon or Plombieres will be found beneficial.

Such is the treatment advised and followed by Prof. Robin, who is no mean authority. It differs from the received treatment in the administration of an effective purgative, large enemas and the suppression of opium.

It is only right to say that in his description of treatment of appendicitis he eliminates infectious appendicitis consecutive to grippe, scarlatina, typhoid fever, traumatic appendicitis, and that due to the presence of foreign bodies in the appendix. All these belong more or less to the domain of surgery.

GERMANY.

Berlin, March 3rd, 1907.

Subcutaneous Injuries of the Pancreas and their Treatment.(a)

This subject was brought forward by Hr. Karewski at the Medicinische Gesellschaft. He recommended the earliest possible surgical interference in all cases of contusions of the abdomen. In such injuries crushing of the liver, spleen and pancreas not unfrequently took place. These contusions sometimes only caused slight symptoms during the first few hours, and if we waited to perform laparatomy until the symptoms were well marked, it would then be frequently too late, as such grave changes would have set in as could lead only to fatal termination.

Injuries to the pancreas, owing to the protected situation of the organ were rare. Garré had only met with thirty such cases recorded, and in only eight was the pancreas the only organ injured. Only three recovered.

The young patient shown had been run over after being knocked down by the shaft of the vehicle, which struck him over the abdomen. He was able to walk home, but abdominal pain soon coming on, he was admitted into the speaker's clinic. Laparotomy was performed at once. The abdomen contained a large quantity of blood, especially in the region of the gastrocolic ligament. By careful exploration the head of the pancreas was found to be crushed. Complete recovery took place. Here, as in all the cases known, the injury to the pancreas was first discovered at the operation. There was no special reason to suspect any injury to the pancreas, as such injuries gave rise to no pathognomonic symptoms, except hæmorrhage into the bursa omentalis with palpable tumour formation. In regard to the point of time at which severe symptoms first appeared, there was no agreement. One should not, therefore, procrastinate when symptoms were undecided, but should do laparotomy at once. Cases which had outpouring of blood and pancreatic juice, but in which the peritoneum was not torn, were the exception. Here a retro-peritoneal hæmatoma was formed, and one could wait. When rupture of the peritoneum did take place, a tumour formed sometimes from retention of the blood in the bursa omentalis; one might also wait in such a case. In deeper tears of the peritoneum, where the blood and juice flowed into the peritoneal cavity, there was danger of general peritonitis. The case led to some interesting physiological results. The patient passed 400 grm. of pure pancreatic juice daily through the fistula and lost a good deal of weight. The secretion being so free, it was difficult to close the fistula. On a fatty anti-diabetic diet as suggested by Wohlgemuth the pancreatic secretion diminished. The diminution was very considerable, and in a comparatively short time, under the application of very strong bactericide remedies to the wound (vioform and airol), the fistula was brought to close up.

Hr. Grouzdew reports in the *Col. f. Gynækol,* 46, 1906, a case of

Retention of a Foreign Body in the Abdomen.

The patient had been operated on for ovarian cyst seven years before. The case ran a normal course. After a year, however, the patient began to have abdominal pains; these increased until she had to seek relief. The pain was mostly by the side of the cervix, where about 2 cm. from it the tip of an iron instrument was felt to be very firmly fixed. The other end of the instrument could be felt in Douglas' pouch. Posterior colpotomy was performed and the foreign body extracted. It proved to be a pair of Ferrier forceps 22 cm. in length. Only the top of the instrument was free. The other part was covered by a firmly adherent membrane, consisting of sclerosed connective tissue.

The operator always after laparotomy washed out an abdominal cavity with artificial serum. In doing this every part of the abdominal cavity was looked after. But such unfortunate accidents were very difficult to avoid. It was curious that the foreign body had never caused any rise of temperature during the whole seven years the patient carried it.

Principles for the Assistance of the School Teacher in the Campaign against Communicable Diseases.

"Grundzüge für die Mitwiskung des Lehrers bei der Beteampfung Ubertragbarer Krankheiten." This is the title of a little work written for the purpose of giving instruction to teachers, and especially those of the elementary schools, in the essentials of the infectious diseases, the manner in which they spread through schools, and the measures that should be taken to arrest the spread of infection. The idea is a good and useful one. One part of the brochure gives a short, clear and intelligible description of the symptoms of the various infectious diseases. The book is published by Julius Springu, Berlin, and costs 1.50 marks.

The Antiseptic Action of Mentsrual Blood.

Professor O. Von Peterson, of St. Petersburg, has an article on this subject, to which a reference is made in the *Deutsch Med. Zeitung,* February 7th, 1907.

Several patients were admitted into the hospital under Professor Peterson's care with numerous soft sores on the introitus vaginæ. A few days afterwards menstruation came on. During the period of the menstrual discharge no dressings were applied to the sores, but they were left entirely to themselves. On the cessation of the period, when the sores were again inspected, instead of the ulcers being worse, as was expected, they were found to be perfectly clean, with well granulating surfaces.

(a) This case was reported on by Hr. Wohlgemuth at the Verein f. Innen Medizin (see Medical Press and Circular).

Systematic observations were now instituted as to the effect of menstrual blood on soft chancres, and the same fact was constantly observed. All the sores that were washed with menstrual blood cleaned up, whilst others near them, but not washed, underwent no change. It is claimed, therefore, by the writer, that menstrual blood has, without question, a distinct antiseptic action.

The action is a specific one; the solvent action of the blood serum takes the bacteria and destroys them as well as the detritus of the surfaces of the wounds.

AUSTRIA.

Vienna, Mar. 3rd. 1907.

Rontgen Rays in Basedowi.

Rudinger has been experimenting with the Rontgen Rays in Morbus Basedowi and agrees with Stegmann that the rays applied to the thyroid gland has a marked effect on its reduction. It should not be constant but alternating as the negative rays are characteristic in the metamorphosis and produce the best results.

Glycosuria.

Brug affirms that the pancreas is not the only gland that produces the saccharine metamorphosis. His experiments accord with Kulz, Falkenberg, and Hirsch, all of whom found by removing the thyroid glycosuria of a severe type was induced often leading to speedy death, which could be arrested or improved by the use of the thyroid tablets. Boldt relates the history of a case occurring in his practice where he had been using pot. iodide for the reduction of a gland which succeeded, but to his surprise the gland no sooner disappeared than glycosuria of a very bad form set in. From this he infers a close connection between the glandular system and glycosuria.

Tetany.

Escherisch gave the clinical history of a case of tetany which has died in one of the spasms since he showed it some time ago to the Gesellschaft der Aertze. It died, he said, from expiratory apnœa, notwithstanding the application of all therapeutic efforts known to the profession. Preparations from the organs of the throat were carefully examined, and the epithelial bodies in the thyroid gland were shown to be quite altered and bleeding profusely. This is the third case within a very short period in which he has been able to prove that hæmorrhage of the epithelial bodies exists in cases of severe tetany.

Hochsinger asked if no hæmorrhage was to be found in other organs of the body, to which he replied that hæmorrhage in the epithelial bodies was usually accompanied with bleeding in the thymus, epicardia and pleura, besides a quantity of pigment being found in other parts.

A Large Boy, but Imbecile.

Knœpfelmacher showed a six-year-old child with the whole body well proportioned and having an excessive growth. His length was 146 cms. or 4 ft. 8 ins., his upper extremities 57 cms., lower 67 cms., the hand 15 cms. and the foot 16 cms. The whole skeleton is strong and well developed; the muscles are equally strong and robust, but the most noticeable point was the extraordinary development of the genital organs which appeared far beyond puberty. He thought there was some connection between this overgrowth and the mental imbecility that existed. Zappert recorded the history of another case from Hudovernig having a similar appearance which he treated with ovarian tablets with a wonderful result. The mind improved, the whole functions of the body became more active and the overgrowth rapidly checked.

Funnel-Shaped Thorax.

Preletner showed a child with a hollow deformity in the anterior wall of the thorax where the sternum was so depressed that a funnel-shaped cavity was formed in the region of the manubrium. It was 3 cms. deep and commenced with a sharp curve at the costal cartilages. The deepest part of the funnel was at the xiphoid process. According to Zucker Randl this deformity is produced in the fœtus by the chin being compressed in utero firmly against the sternum. Hageman on the other hand attributes this to the pressure of the heel on the part in a narrow uterus, while Ebstein thinks the deformity is hereditary, due to a suppression of growth. Heuter considers the rhachitis sufficiently accounts for the organic changes. No hypertrophy was present in the right ventricle.

HUNGARY.

Budapest, March 3rd, 1907.

At the recent meeting of the Budapest Royal Society of Physicians and Surgeons, Dr. Hasenfeld read a paper on the

Etiology of Aneurisms of the Aorta.

He said that aortic aneurisms caused by trauma in perfectly healthy individuals are very rare, but certainly do occur. He believes that small tears are replaced by cicatricial tissue which cannot withstand the continuous pressure. The injury is generally very severe, and directed against the thorax. Infectious diseases as a cause are of more importance in the smaller vessels than in the aorta, but it is possible for an infectious thrombus to lead to ulceration with weakening of the walls or for an acute aortitis to be followed by predisposing chronic changes. Alcohol, nicotine, lead and senile atheroma all play a subsidiary role as compared with syphilis. The pathological study of almost all aneurisms will show lesions characteristic for lues, and ruptures of the elastic membrane, as have been described by others, are hardly ever seen.

Dr. Vas spoke on the

Titration of the Gastric Juice.

Volhard was first, who observed that if some albumin is added to gastric juice, phenolphthalein will eventually give much higher values than at first, and the change of colour will take place considerably later than with litmus. Dr. Vas explains this with the fact that peptone binds alkali just as readily as it does acid, and that phenolphthalein indicates only the presence of free alkali. It is therefore much more accurate to determine the total acidity with alizarine or with red and blue litmus paper. The author further said that Töpfer's method is based on wrong principles, but gives fairly accurate results; the alizarine does not indicate the free hydrochloric acid, but the total acidity, and by subtracting the phenolphthalein figures from those obtained which is about the same as the combined acid.

Dr. Preisich discussed the question of

Acid Creamless Milk in Gastro-enteritis.

Since 1898 the most strenuous efforts by intestinal lavage, water diet, baths, astringents, etc., have been made by Dr. Preisich to overcome the gastro-enteritis of infants. But in spite of the most devoted care the mortality up to last May was in the neighbourhood of 50 per cent. At that time the treatment was changed to milk deprived of cream by centrifuging and acidified by pure cultures of the lactic ferment. From 30 to 60 cc. of this were given at each feeding. The cases treated were those of grave prognosis characterised by very profuse diarrhœa, rapid emaciation, bad general condition and high fever. In a remarkably short time the temperature subsided, vomiting ceased, the diarrhœa diminished, the stools becoming normal in forty-eight hours in some cases, and the weight was most noteworthy; other children treated at the same time by the older methods showed a rapid wasting. Out of fourteen almost hopeless cases, thirteen recovered. The milk was prepared at the local Pasteur Institute.

Dr. Behrend reports a case in which an infant was affected with a primary pyelitis. ("Orvosok Lapja Physician's Paper.") This affection may be readily overlooked, as the urine of babies is rarely examined.

Dr. Behrend's case had such a clinical picture that closely resembled typhoid. The symptoms consisted of a gradually increasing fever, which continually returned, even after the administration of antipyretics. This could not be accounted for by anything found on repeated physical examinations until the urine was carefully examined. This was found cloudy and full of bacilli and pus corpuscles. The treatment consisted of various antipyretic measures and bromide of sodium to guard against eclamptic seizures. Urinary antisepsis was secured by urotropin and turpentine. A cure resulted in from three to four weeks. The author, Dr. Behrend, advises that in every case of continued fever in a baby, where all other sources can be eliminated, including typhoid, the urine be carefully examined microscopically. Secondary pyelitis is common enough, but a primary form is rather rare, and should always be borne in mind in doubtful cases.

FROM OUR SPECIAL CORRESPONDENTS AT HOME.

SCOTLAND.

Edinburgh Royal Asylum.—Annual Report.—In his report for 1906 Dr. Clouston states that 1259 patients have been under treatment during the year. There were 385 admissions (169 men and 119 women), and 140 deaths (55 men and 85 women). Only 35 of the patients admitted were in really good bodily health. The number of cases of general paralysis was 55, or 9 less than last year. Dr. Ford Robertson and Dr. McRae, working in the Scottish Asylums Laboratory, had made distinct progress towards a true knowledge of the nature of this most fatal disease, and they hoped of its treatment with a view to cure. The patients they had had under treatment had, where the disease was in an early stage, shown a wonderful improvement; but the first thing to be done was to be able to diagnose it definitely in its earliest stages, so that treatment might be applied before the brain was seriously damaged. Had they a sure means of recognising the malady at its earliest stage, there seemed good scientific reason now for the conclusion that under specific treatment it might be arrested. Alcohol was, as usual, the commonest of all the outward causes of insanity. It was given as a cause in 29.5 per cent. of the male admissions, and 16.2 of the women. Taking that definite form of insanity called "alcoholic insanity," the percentage was 18 among the men, and 10.8 among the women admitted. The fact that of the total admissions to the institution during the 42 years 1864–1905, the majority of the patients were women was somewhat remarkable. He also commented on the low recovery rate—88 patients, and the rather high mortality. This resulted from the numbers of senile, paralysed and broken-down patients admitted. Heading the causes of death stood tubercle, chiefly among the rate-paid patients. Cray House still enjoys the credit of having had no deaths from tuberculosis since it was opened twelve years ago. The year 1907 marks the centenary of the asylum, its Charter having been granted in 1807. The poet Ferguson, the precursor and inspirer of Burns, went mad and died amid squalid surroundings in the old city Bedlam in 1774. This sad spectacle aroused the sympathy of Dr. Andrew Duncan, senr., Edinburgh's great medical philanthropist. He wrote a "proposal for establishing a lunatic aslyum in the neighbourhood of the City of Edinburgh" in 1792, and as a result, a body of trustees collected subscriptions and obtained a charter in 1807. The building was opened for patients in 1813. In no department of human effort to benefit humanity did a spirit of hopeless pessimism do more harm than in the treatment of the insane, and in no department was optimism more helpful. Commenting on the problem of the prevention of insanity, Dr. Clouston said technical insanity was the acme and caricature of the foolishness and weakness of mind which more or less pertained to all men, but it was not true that "all men are mad." That was a loose, if tempting, aphorism which gave a wrong impression of what man is, and of what madness is.

Cerebro-Spinal Meningitis.—In Edinburgh the disease shows no signs of abating. There have now been between 20 and 30 cases, nearly all of which have terminated fatally. A ward has been set apart in the city hospital for the reception of the disease, and the Town Council have issued a circular making the Infectious Diseases (Notification) Act applicable to cerebro-spinal meningitis for a period of six months. The majority of the patients, so far, have been children, and a number of them have been treated in the Sick Children's Hospital. The directors, however, have decided that in future cases are to be sent to the Fever hospital, as soon as the bacteriological diagnosis is made. It may not be amiss to point out that in many of the cases, even when acute, the symptoms of meningitis have been comparatively slight—a little stiffness of the neck, or pain on moving the head—and to a great extent masked by the constitutional disturbance. The bacteriological diagnosis of the disease, however, is extremely readily made. Lumbar puncture is a most simple and harmless procedure and should be employed in any doubtful case. If the fluid is turbid this is practically sufficient for a diagonsis, and where a smear is made and stained in the usual way with Leichmann's stain or otherwise, the meningococci can be recognsied without any difficulty. The disease really differs very widely in its clinical manifestations from tuberculous meningitis; so much is this the case that as we understand that during the present epidemic in Glasgow only two cases of tuberculous meningitis, have been sent into the Fever Hospital as cases of the epidemic cerebrospinal form. Practical experience therefore, shows that mistakes are not so frequent as might have been anticipated.

The Multiplication of Health Congresses.—If the banding together of health experts be a sign of the development of what Dr. Clouston has happily termed "a health conscience," the author of the phrase should be gratified that his object will soon be attained, for no one can have failed to note that "Health Congresses of all kinds, like mushrooms, spring up almost without warning, and afford, *inter alia*, many opportunities for civic delegates going on an agreeable jaunt, in which pleasure and business are skilfully compounded, at the expense of the long-suffering ratepayer. We are glad, therefore, to note that another conference of delegates from various Scottish corporations, *absit omen*, was held in Edinburgh last week, with a different object. It considered whether steps could not be taken to reduce the number of sanitary and other conferences which take place annually in different parts of the country. It was unanimously resolved "That in the opinion of this Conference it is very uudesirable that the Royal Sanitary Institute and the Royal Institute of Public Health should hold separate congresses every year," and "that a representation be sent to the Royal Sanitary Institute and the Royal Institute of Public Health urging these bodies to make an arrangement for holding a combined Congress, or holding their respective congresses in separate years.

Dr. J. M. Beattie, senior assistant to the Professor of Pathology in the University of Edinburgh, and Lecturer on Bacteriology, has just been appointed to the new Professorship of Pathology in the University of Sheffield. Dr. Beattie has already won his spurs as an investigator and a teacher and his appointment has been very popular. Much as his many friends will miss him from Edinburgh, they none the less join in congratulating him on his well-deserved promotion, and wishing him and his new university all success and prosperity.

BELFAST.

Cerebro-spinal Meningitis.—The outbreak of cerebro-spinal meningitis in Belfast shows no signs of having spent its force as yet. During the past week there were over thirty new cases reported, and twenty deaths. Several of the cases reported were of fulminating type, proving fatal before the patient could be removed to hospital. Every effort is being made by the authorities to check the progress of the disease, and the City Coroner holds inquests on those cases which have died without medical attendance, emphasising in his remarks to the jury in every case the absolute necessity of proper care for the sick. The total number of cases up to date is about 130, with 75 deaths. In Dublin we believe that two fresh cases have occurred during the past week, making a total of 12 cases with nine deaths.

Public Health.—"Coming events cast their shadows before," says the poet, and the truth of his statement can be abundantly verified in Belfast just now, where preparations are going on in many different quarters for the approaching Commission of Inquiry into the health of the city. The Corporation had a long and acrimonious debate on the subject and have arranged to employ two members of the bar to defend them, as they say they will be on their trial, which is perfectly true. The Citizens' Association and the Christian Civic Union are both considering the question of evidence before the Commission, and Dr. Calwell, ex-President of the Ulster Medical Society, has just issued in pamphlet form, with preface and notes, extracts from communications which he has made to medical journals and societies during several years past, all bearing on the public health question. The pamphlet will prove a most useful source of information to all interested in the subject.

Belfast Maternity Hospital.—The 113th annual meeting of this old charity was held last week, the Countess of Shaftesbury presiding. The medical report, read by Dr. Osborne, showed that 373 patients had been treated in hospital during the year—317 children were born, 160 males and 157 females. There were 21 still-born, and only one maternal death, that being a case of placenta prævia, admitted when almost moribund. In the extern department 310 women were attended in their own homes. The treasurer's report showed that while the ordinary income was £300 less than their expenditure, they had managed, with the help of a bazaar, to reduce the balance against them to £20.

Society for Providing Nurses for the Sick Poor.—The annual meeting of this Society was held last week, the Lord Mayor (the Earl of Shaftesbury K.C.V.O.) presiding. The report showed that during the year the nurses had attended 1,123 cases and had paid 33,932 visits. Dr. R. W. Leslie voiced the feeling of the medical men of the city in testifying to the very high opinion he had formed of the work done by the nurses, and several clergymen expressed the same opinion.

LETTERS TO THE EDITOR.

THE QUACK MEDICINE TRADE.

To the Editor of the Medical Press and Circular.

Sir,—The editor of one of the medical papers in his issue of this week asks "how long the Legislature will consider it consistent with the public health and well-being to allow the owners of 'patent medicines' to foist their wares upon the community?" The answer to this question is that the present state of things will continue until the medical profession takes steps to promote a change. Statesmen and politicians who compose the Legislature, as well as the whole of the educated public, are ignorant of the nature and extent of existing evils, and owing to the capture of the newspaper press by quacks, cannot gain enlightenment through any existing medium. The facts can be brought home to the public only through the medium of a Royal Commission. No one who examines the question fully can fail to recognise that the case for medical law reform will need demonstrating before it will stand a chance of being taken up by Parliament. The profession alone at present are able to appreciate the facts; they know that new legislation is called for far more for the protection of the public than the advantage of medical practitioners, it is their duty on humanitarian grounds alone to fight for reform. They have always fought for sanitary progress, and the more strenuously always when the prevention of disease was from the sordid point of view opposed to their own interests.—I am, Sir, yours truly,

Henry Sewill.

March 1st, 1907.

JUVENILE SMOKING.

To the Editor of The Medical Press and Circular.

Sir,—May I call the attention of your readers to the fact that the Day Schools Sub-Committee of the London County Council has had under consideration the question of juvenile smoking, and has just reported to their authority. They have dismissed the idea of legislation, the proposal to issue a circular to parents and guardians, and the suggestion of influencing children through teachers in elementary schools. The Committee have satisfied themselves that smoking by children prevails very widely, and have accepted the truth of the allegation that the habit forms a powerful factor in stunting growth and in producing disease. The Committee recommend that the County Council support the existing movement for legislation for the suppression of juvenile smoking, and propose to prepare a suitable leaflet for distribution among parents and school teachers. In the present state of the legislative machine, it seems a little doubtful whether the suggested new law lies within the sphere of practical politics; but a vigorous propaganda among parents and guardians, and among boys themselves, might produce results worth working for. Many sensible boys who err entirely through ignorance would refrain from smoking if once enlightened as to the hurtfulness of the habit. I think, Sir, this question evidently worthy of discussion by the readers of a medical journal.—I remain, yours faithfully,

Nestor.

MEDICAL ETIQUETTE.

To the Editor of The Medical Press and Circular.

Sir,—Can you or any of your readers bring enlightenment to my perplexed mind with regard to the following point of medical etiquette. I have always understood that it is contrary to such etiquette to send the reports of ordinary scientific meetings of medical societies or to send medical books for review to the lay press, or to advertise medical books in the lay press, and yet within the past few weeks glaring examples of these three proceedings have occurred, without provoking medical comment.

In a Dublin daily paper, the *Freeman's Journal*, some three weeks ago there appeared a fairly full report of the meeting of a medical society belonging to one of the Dublin medical schools. The report not only gave the substance of what each speaker had said, but announced the agenda for the next meeting. Indeed it was so full as to suggest that it had been contributed to the paper in question by one of the officials of the society. I may further mention that the meeting in question was an ordinary one, and not any special meeting which possibly might have been of interest or value to the general public.

In another Dublin paper, the *Irish Times*, a few days afterwards, I noticed a review of a large Atlas of Anatomy, edited by a well-known anatomist, and published by a highly respectable firm of publishers.

Finally, in a London weekly journal, the *Spectator*, I find the advertisement of a work on ophthalmology by one who, I believe, is an ophthalmologist of high standing in his profession.

These three cases have led me to wonder whether the opinion I had previously held of the inadmissibility of such practices is a correct one. Correct or incorrect, it is shared by a number of medical writers, who lose popular fame and notoriety by refusing to permit their books to be advertised and reviewed in lay journals, and by a number of medical societies who lose similar fame and notoriety by not sending a record of their doings to lay journals. If my opinion is incorrect, why should they lose this notoriety? If, on the other hand, my opinion is correct, then, Sir, I suggest that some authority, either the medical press, the Royal Colleges, or the General Medical Council, should convey a stern reproof to these gentlemen who presumably act, or whose publishers act for them, in a manner contrary to medical ethics, and to such societies as act in a similar manner.—I am, yours, &c.,

X.

THE ORGANISATION OF POOR LAW MEDICAL RELIEF (OUTDOOR).

To the Editor of the Medical Press and Circular.

Sir,—In a few days there will be an election of guardians. May I impress upon your readers the importance of securing the nomination and election of candidates who are in favour of out-door relief of Deserving Aged Poor where practicable, and of making such out-relief adequate.

The Local Government Board itself issued a circular to this effect in August, 1900 (which may be bought for 2½d.), and until old-age pensions can be obtained, this is far better than offering to the veterans of industry a painful choice between the workhouse and starvation or at least great destitution. Also, it is most important to elect guardians who will give outdoor medical relief (in the first instance) to all poor persons unable to pay a doctor, without placing obstacles in the way such as making the relief a loan, or requiring the patient (or in the case of a child, a parent) to appear before the Guardians. Of course, when the doctor has seen the patient he can decide whether it is a case to be treated at home, or in the Poor Law or some other infirmary or hospital. The great point (for the public health) is to take care that cases of illness come before the doctor at a very early stage. By this means we may check infectious diseases such as measles, whooping cough, fevers of various descriptions and phthisis. Cutting down medical relief is dangerous to the public health.

Yours faithfully,
J. Theodore Dodd,
A Guardian and Councillor of the
City of Oxford.

March 2nd, 1907.

OBITUARY.

ERNEST EDWARD KING, M.R.C.S., L.S.A.,

On Monday morning the death occurred at Broad Street, Ludlow, of Mr. Ernest Edward King, after a short illness. Deceased was registered on December 18th, 1879, and was Licentiate of the Society of Apothecaries, London, 1879, and member of the Royal College of Surgeons (England), 1881. He came to Ludlow over twenty-four years ago as assistant to the late Mr. Henry Hodges, surgeon, Broad Street, and after a few years he commenced to practise on his own account, and soon built up a large connection. He was of a kindly and genial disposition, and during his residence at Ludlow he made many friends. He was thoughtful and kind to the poor, and during the late severe weather he opened a private soup kitchen at his own house, where he had from 50 to 60 of the poor children and fed them. He was a Churchman and a strong Conservative. He was a fluent speaker and during the last General Election he rendered yeoman service in the cause of Mr. Rowland Hunt, M.P. He was chairman of the Broad Street Ward Conservative Committee. About a fortnight ago he was out on his rounds when he had a sudden seizure of the heart. He was brought home, and the best medical advice was obtained, and on Sunday last it was hoped he was improving, but on Monday morning he had another attack which proved fatal. Much sympathy is expressed for his widow and son and daughter. On Thursday morning at 6.45 the remains of deceased were removed by train to Saffron Walden, Essex, for interment. The members of the family, Mrs. King (widow), Mr. Eric and Miss Ena King (son and daughter), Mr. Arthur King and Mr. Herbert King (brothers), and Miss Davenport, left Ludlow on Wednesday evening. The funeral took place on Thursday afternoon, at Saffron Walden. A large number of beautiful wreaths were sent.

THOMAS HATFIELD WALKER, L.R.C.P., L.R.C.S.Ed., F.C.S.

We regret to announce the death of Dr. Thomas Hatfield Walker, Newcastle. Dr. Walker was born at York in 1850, and was educated at the University of Edinburgh. About twenty-five years ago he came to Newcastle, but while taking no prominent part in public affairs he was warmly interested in subjects relating to hygiene and the physical well-being of the people. For many years he acted as public analyst to the city of Carlisle, and was also toxicological chemist for Newcastle. He was an expert in water analysis, and introduced a new method of estimating nitrates in water. He wrote numerous papers in scientific journals on sewage irrigation, disinfectants, and other subjects connected with public health.

SPECIAL ARTICLE

THE HEALTH OF DUBLIN.

The Report of Surgeon-Colonel Edgar Flinn, Medical Inspector of the Local Government Board, on the sanitary condition of Dublin (*a*) which, in spite of its being dated 1906, was only issued to the public a few days ago, is a document of importance. Surgeon-Colonel Flinn has inquired into the subject from many points of view—sanitary, social, and economic—and his conclusions should be of much practical value to an energetic Public Health Department.

The area included in the City of Dublin is 7,894 acres 2 roods 10 perches and the estimated population at present is 293,385 persons. The average density of the population is, therefore, 37.1 persons per acre.

The geological formation is nearly altogether drift, except in the vicinity of the Liffey, where there is a deposit of river gravel.

Surgeon-Colonel Flinn gives a table of the population in 1901, classified according to occupation. More than one-half of the entire population come under the heading of "Indefinite and Non-productive," whereas only about one-fourth is "Industrial."

Two Commissions of Inquiry have in the past considered the health of Dublin. In 1879 a Royal Commission was appointed whose chief concern was with the system of sewerage. In its Report special attention was drawn to the insanitary condition of the tenement houses, and to the presence of slaughter-houses in improper places throughout the city.

In 1900, on the suggestion of Earl Cadogan, then Lord Lieutenant of Ireland, a Committee was appointed by the Local Government Board to report upon the causes of the high death-rate and the measures which might be taken to improve the health of the city. The report of this Committee contained eighteen important recommendations, dealing with such serious matters as the condition of tenement houses and of housing the poor generally, the scavenging of streets and lanes, slaughter-houses, public baths, provision of hospital accommodation for infectious diseases and the reorganisation of the Department of Public Health. Surgeon-Colonel Flinn states that "the Public Health Committee concurred in very many of the recommendations made by the Committee and efforts have been made to carry out some of these recommendations."

(*a*) "Report on the Sanitary Circumstances and Administration of the City of Dublin, with Special Reference to the Causes of the High Death-rate." By Surg.-Col. D. Edgar Flinn, F.R.C.S., D.P.H., Medical Inspector of the Local Government Board for Ireland. Dublin H.M. Stationery Office. 1906.

Of the eighteen recommendations four have been followed, five have been partially carried out, while no steps have been taken with regard to the other nine.

During the period 1895–1905, the average annual death-rate in Dublin has been 27 per 1,000. In Belfast it has been 22.3, in London 17.7, in Liverpool 22, in Manchester 21.6, in Edinburgh 16.7, and in Glasgow 20.7.

The death-rate in Dublin from all causes exceeds by a great deal, therefore, that of the other large towns. During the past five years no less than 6,245 deaths were registered in Dublin from phthisis, and 3,019 deaths were registered from other forms of tuberculous disease. During the same period the average annual death-rate from all causes has been declining throughout the United Kingdom. Dublin has participated in this decline as regards its death-rate from all causes as well as from zymotic diseases. The death-rate from phthisis still remains at a very high standard, and exceeds that of all other cities and towns in the kingdom. During the past ten years it has shown no tendency to decline; if anything the death-rate from this cause has shown an upward tendency, and it yet remains one of the principal causes that is accountable for keeping the Dublin death-rate so high above a normal standard.

The question of a sanatorium is at present engaging the attention of the Public Health Committee. Of its necessity there can be but one opinion, having regard to the large number of deaths that are yearly occurring in Dublin from tuberculous diseases.

Diseases of the organs of respiration (exclusive of phthisis) are accountable for a large number of deaths in the City of Dublin. A large percentage of cases occur amongst the poorer classes—insufficient clothing, exposure, and privation being fruitful causes of these diseases.

In the year 1900, 1,608 deaths were registered from diseases of the respiratory organs; 1,544 deaths occurred in 1901; 1,654 in 1902; 1,436 in 1903; and in 1904, 1,469 deaths were registered from these affections.

The deaths of children under one year of age per 1,000 births in the period 1894–1904, have been 161.4 per annum in the North Dublin Union, and 173.7 in the South Dublin Union. There are many contributory causes of infantile mortality in Dublin, most of which were preventable, but there is one which apparently exceeded all others in potency, viz., the prevailing and widespread ignorance amongst mothers as to the proper feeding of infants, and also to grave alimentary conditions brought about by wrong feeding.

There has been a remarkable decrease in the number of cases of typhoid fever in the past few years. Thus from 1,038 cases in 1900 there has been a steady decline to 437 in 1905 and the deaths have declined in the same period from 99 to 40.

Surgeon-Colonel Flinn speaks highly of the purity of the Dublin water supply. He believes, however, that the disuse of the old pump-wells throughout the city, in use previous to the introduction of the water supply, has rendered the subsoil of Dublin waterlogged. Such a condition may have a serious effect on the health of the city.

The entire sewerage of the city, which hitherto discharged directly into the Liffey, will henceforward be conducted in a main sewer to the Pigeon House. It will there be purified, the clarified effluent being discharged into the open sea, and the sludge carried by barges and deposited in the sea some miles out.

But little improvement has been made in the system of public and domestic scavenging. Dust-bins are not collected daily, watering of the streets is insufficiently performed, and the sweeping of dry streets by the machine brush is both a nuisance and a danger.

Dairy regulations are fairly well carried out, but there is room for considerable improvement. Much milk, however, arrives from the country, from cow-houses which are not under supervision of any sort.

Surgeon-Colonel Flinn makes an elaborate investigation of the social and economic conditions of the poor in Dublin, and of the attempts which have been made to improve them. He states that "the wage earned by the average labourer in Dublin is inadequate to maintain a family in a state of physical efficiency."

He quotes the opinions of the Medical Superintendent Officer of Health, and the District Medical Officers of Health on the subjects of his inquiry, and he details the duties performed by the staff of sanitary sub-officers.

He concludes that it is quite clear that the chief causes which contribute to the high death-rate in Dublin are:—poverty, with its attendant evils; tuberculous disease, intemperance, insanitary conditions under which the poorer classes live, overcrowding, and want of knowledge in the feeding and care of infants.

He recommends various measures for dealing with these evils, including improved water supply to tenement houses, improved housing of the working classes, daily removal of the contents of dust-bins, strenuous measures against tuberculosis, the removal of slaughter-houses from their present sites, and the better control of the meat and milk supplies.

The Report is illustrated by maps showing the geological formation of the neighbourhood of Dublin, and the areas of greatest poverty of the city.

REVIEWS OF BOOKS.

CLOUSTON ON THE HYGIENE OF THE MIND. (a)

Dr. Clouston's "Hygiene of the Mind" is one of the earliest numbers of the New Library of Medicine which Messrs. Methuen and Co. are publishing. This library is avowedly popular in aim, its object being to present medical problems of general interest in such form that thoughtful people without scientific training can grasp them and receive authoritative guidance as to the correct attitude to adopt. To judge this book fairly, then, it must be constantly borne in mind that it is not written for the alienist or even for the medical practitioner, but for the intelligent layman. Now the hygiene of the mind is, as a distinctive science, something of a novelty, and to present a new science in acceptable form to the non-scientific person requires an amount of courage and earnestness which can only spring from strong belief. Dr. Clouston writes with a confident touch which bespeaks not only conviction but a desire to impart that conviction to others, and there is no doubt that there are a great many people, especially such as have the guidance of youth, to whom this book should be instructive, stimulating, and—if we may venture so far—corrective. A great deal that Dr. Clouston says may seem trite enough to the family doctor, but it will be fresh enough to those into whose hands the book should fall, and they will learn roughly what is the prevailing opinion of the bulk of the profession on the topics dealt with. Indeed, Dr. Clouston, if not daringly original, is comfortably free from fads; his advice is always temperate, sane and sound. We greatly admire the ability with which he has evaded expressing any definite views as to the mind itself; no decisive view is called for in a treatise of this kind, and would if expressed tend to create prejudice, for does not everybody know his own mind? Dr. Clouston has skated over very thin ice, and though he inclines now to the materialistic, now to the idealistic, he never plumps for either, and we think he is very wise. So, too, with regard to religion. He combines insistence on using the religious emotion in education with a scientific exposition of the parts of religion which may judiciously be kept in the background; yet he never commit himself. Again we think he is very wise. Throughout the pages there is a good deal of interesting gossip—anecdotes, personal experiences, and apt illustrations—while here and there we light on a good epigram, such as (p. 214): "The safest marriage always consists of a mutual admiration society of two." Is it not rather a pity—in fact, rather more than a pity—in a book designed to help mental culture, to express the pessimistic doctrine (p. 205) that, "The saving grace of common sense is not one, unfortunately, that can be acquired by any amount of care or resolution"? Perhaps it is not, but then what is the use of mental hygiene? We cannot help being surprised that a literary Scot such as Dr. Clouston should express the view that it is doubtful if the author of "The Cotter's Saturday Night" knew that excesses tended to shorten life, and it is questionable whether scientific men can side with the splendidly poetic, but highly fanciful view of Keats' death that Shelley gives us in "Adonais." And while we are on the subject, does not Plutarch more than suggest that Alexander the Great died of typhoid? That, at least, has always been our own view. But this book, take it all round, is a sensible, timely, and instructive one, and the world would be a brighter and happier place if everybody lived up to its teaching.

(a) "The Hygiene of the Mind." By T. S. Clouston, M.D., F.R.S.E., Lecturer on Mental Diseases in the University of Edinburgh, etc. Ten illustrations. London: Methuen and Co. 7s. 6d. net.

HUMAN ANATOMY. (*a*)

It is difficult to speak temperately about Dr Sobotta's "Atlas and Text Book of Human Anatomy." To turn over its pages and to pore over its plates makes us wish to become students again, so that we might have the luxury of learning anatomy under conditions undreamed of when we started removing the fascia from the pectoralis major, and picking out the relations of the axillary artery. To say that we have never seen such accurate, helpful, life-like illustrations in anatomy sounds like using the language of exaggeration; but it is no more than the truth. This book is rightly designed an Atlas and Text-book, because the text is obviously complementary to the plates, which stand out as the commanding feature of a noteworthy volume. But we do not mean that the text is not good in itself; it is not only good, but very clear and accurate, for, though it does not deal with anatomy in its comparative and developmental sides, such as is needed for the higher examinations in this country, it is sufficiently comprehensive to supply the student with all he needs for the ordinary tests. And indeed, to give a complete survey of the anatomical field would have enlarged the book beyond reasonable and practicable limits. No student of the higher anatomy, no surgeon or practitioner, however, will ever regret buying it, for he can not only find all that is wanted in the way of regional anatomy, but he will be able at a glance to see exactly the parts he wants to see in their natural position and relations. The proverbial busy practitioner who has the work in his possession will have frequent occasion to rise up and call the publishers blessed, for having provided a ready-made (and odourless) dissecting-room at his elbow. The only drawback—and that is a slight one—is that the terminology occasionally differs from that current in anatomical schools in this country, but the editor claims that as these terms are the terms of the future it is worth while acquiring them. As to the plates themselves, they are all produced from actual photographs, so that the stereoscopic effect is given, and they have been artistically and discriminatingly coloured, so that each structure is allowed its full value. As a plate of the actual size to be used in the book was employed in the preparation of the photographs, the relative parts of structures are each precisely proportioned. We can only say that we can conceive of no more perfect illustrations being produced by any of the arts at present in use. Perhaps in fifty years fresh resources may enable the student to learn anatomy without the trouble of thinking, but in the meantime we can recommend this atlas as a bargain he will never regret.

MEDICAL NEWS IN BRIEF.

Lichfield Medical Man and his Fee.

At Lichfield, on February 27th, Dr. Rowland made an application to the city justices, under Section 285 of the Lunacy Act, 1890, for an order to be made on the Lichfield Guardians for a fee of one guinea for examining into the mental state of a woman on November 13th. Dr. Rowland is medical officer of the workhouse, and Mr. D. Harrison, who is a member of the Guardians, was the magistrate who saw the case with him. He claimed a fee of one guinea, but Mr. Harrison only allowed half a guinea as there was another case at the same time. The doctor wrote to the Guardians, asking for an order to be made, but they said they could not interfere, considering it to be purely a matter between Mr. Harrison as the magistrate and the doctor as a private practitioner. Dr. Rowland said Mr. Harrison knew the views of himself and other medical gentlemen in Lichfield and recognised that the fee for examining a patient, whether sent to the asylum or not, was a guinea. Mr. Harrison accepted his services as a private practitioner, and should pay the fee. Mr. Harrison said the Act stated that a justice should use his own discretion and allow what he thought was a reasonable fee. Mr. Keyte, relieving officer, really called in the doctor. He did not consider the patient was insane, but that it was merely a case of temper.—The Court took no action, Mr. Harrison promising to pay under protest if his views were clearly stated in black and white.

Remarkable Action.

An action presenting somewhat singular features was tried at the Manchester Assizes during last week. The plaintiff claimed damages, under Lord Campbell's Act, for the death of her daughter, which had been caused, as she alleged, by the negligence of the defendant, a dentist. The mother took the child, aged 9, to the defendant on August 30th. Three teeth were taken out at the time, but only one was found. The child at once complained of pain, began to cough, and speedily developed septic pneumonia, from which she died on September 23rd. For some unexplained reason no post-mortem was made, and although it must be presumed an inquest was held, no mention was made of one at the trial. The medical evidence supported the theory that one of the teeth had slipped into the windpipe and passed into the lung. It was stated that the condition of the child's throat made it certain a tooth had passed down; but the reported evidence is too general and vague to be of value. In the end the jury stopped the case on the ground that no negligence had been proved, and judgment for the defendant was recorded.

Illegal Operations.—Treasury Prosecution.

At Marlborough Street, Caleb Charles Whitefoord, 63, a disregistered medical practitioner, living in Upper Marylebone Street, W., surrendered to his bail on February 8th to answer the remanded charge of having performed illegal operations on women whose names, with one exception, were suppressed. Mr. Muir, instructed by Mr. William Lewis, prosecuted on behalf of the Treasury; and Mr. Forrest Fulton appeared for the defence. Several women spoke to having paid visits to Whitefoord, and described what happened. One of them, thickly veiled and apparently very ill, swooned in the witness-box and had to be carried out of court. Mr. Muir, having been informed that she suffered from epilepsy, said he would dispense with her evidence altogether. Mr. Denman, after evidence had been given at great length, again remanded the prisoner on the same bail as before—one surety in the sum of £500.

Is Paregoric a Poison?

A curious case was heard at Bridlington County Court last week, before Judge Dodd, when the wife of Mr. J. W. Wilcock, registered chemist, was sued by the British Pharmaceutical Society for having sold

---

(*a*) "Atlas and Text-Book of Human Anatomy." By Dr. Johannes Sobotta, Professor of Anatomy in the University of Würzburg. Edited, with additions, by J. Playfair Mc urrich, A.M., Ph.D., Professor of Anatomy in the University of Michigan. Vol. I. Bones, Ligaments, Joints, and Muscles. 320 illustrations, mostly in colours. Philadelphia and London: W. B. Saunders and Co. 1906. 25s. net per volume.

poison to P.C. Bell, inspector under the Food and Drugs Acts, the penalty against an unqualified person being £5.

Mr. Laverack, for the plaintiffs, said the preparation sold was paregoric, which contained opium, and was scheduled under the Act. Mr. Baynes, public analyst, confirmed the statement.

Mr. Wilcock argued that paregoric was not a preparation of opium inasmuch as it did not contain a poisonous quantity of the drug.

His Honour held that the plaintiffs had proved that paregoric was a poison, inasmuch as it contained enough opium, beyond a doubt, to poison some children, and that it was included in the schedule of the British Pharmacopœia. The case was a very important one, and he would place every facility in Mr. Wilcock's way if he desired to appeal.

The Viewing of Dead Bodies.

Mr. Luke White, Liberal M.P. for the Buckrose Division of Yorkshire, has given notice that he will introduce in the House of Commons a Bill to dispense with compulsory viewing of bodies on the holding of coroners' inquests.

Dr. Hebert freshly charged.

The Guérin-Hébert case will now probably enter upon a new phase Dr. Hébert, who was to have been liberated yesterday evening, was kept in custody in consequence of a new charge, namely, that of having furnished Germany with certain papers and photographs of places on the French coast.

Irish Poor Law Reform.

The Royal Academy of Medicine in Ireland has passed a resolution expressing its approval of the suggestion in the report of the Lord Lieutenant's Poor Law Commission, that the entire Poor Law medical service in Ireland should be converted into a national service to be paid by the State, the service to be entered by a competitive examination and the members to be jointly controlled by the central body and the local bodies, the medical profession having representation on the central body.

Medical Sickness and Accident Society.

At the usual monthly meeting, held on 22nd ult., there were present: Dr. de Havilland-Hall, in the chair, Dr. M. Greenwood, Mr. W. Thomas, Dr. W. K. Sibley, Dr. J. Brindley James, Dr. J. W. Hunt, Dr. F. S. Palmer, Mr. F. S. Edwards, Mr. J. F. Colyer, Dr. St. Clair Shadwell, Mr. F. Wallace and Dr. J. B. Ball. The recent epidemic of influenza has largely increased the Sick Pay disbursements during the early part of the year, and in January amounted to the largest sum ever paid away in any month of the Society's working. The claims, though numerous, have been of short duration, and their total will make no appreciable diminution of the Society's reserves, which now amount to over £200,000. The number of members drawing half-pay, many of whom will probably never be able to resume work, is still growing.

London Inter-Collegiate Scholarships Board.—Entrance Scholarships and Exhibitions, 1907.—University College, King's College, and the East London College.

A combined examination for Entrance Scholarships and Exhibitions tenable at University College, King's College, and the East London College will be held in London by the London Inter-Collegiate Scholarships Board on Tuesday, 14th May, 1907, and following days. The competition is limited to those who have not previously been students at any one of the colleges, *except where the contrary is stated.* No competitor can be elected to more than one scholarship or exhibition. No candidates will be admitted to the examination for these scholarships and exhibitions unless they have passed the Matriculation Examination of the London University or any examination accepted by the University in lieu thereof, or are the holders of a School Leaving Certificate, or are able to furnish some evidence of having had a sound general education which is satisfactory to the Board. Application should be made to the Secretary of the London Inter-Collegiate Scholarships Board, University College, Gower-street, London, W.C., for forms of entry, which must be filled in and returned together with a certificate of age and one of good conduct from the principal of the candidate's last school or other satisfactory reference not later than 1st May, 1907.

The total value of the scholarships amount to over £1,500.

Prize for Industrial Hygiene.

The Council of the Society of Arts are prepared to award, under the terms of the Benjamin Shaw Trust, a gold medal or a prize of £20. The medal, under the conditions laid down by the testator, is to be given "for any discovery, invention or newly devised method of obviating or materially diminishing any risk to life, limb, or health incidental to any industrial occupation, and not previously capable of being so obviated or diminished by any known and practically available means." Intending competitors should send in descriptions of their inventions not later than December 31st next, to the Secretary of the Society of Arts, London.

PASS LISTS.

Royal College of Physicians and Royal College of Surgeons, Ireland.

The following candidates have gained the Diploma in Public Health:—Major E. G. Browne, L.R.C.P., F.S.I., R.A.M.C., John G. Devane, M.B.R.U.I., Capt. A. Leventon, F.R.C.S.I., I.M.S., with honours, T. Nicol, M.B.Edin., with honours, M. J. Russell, F.R.C.S.I., Major G. W. Tate, M.B.Dub. Univ., R.A.M.C., A. A. Woods, L.R.C.P.&S.I.

Royal College of Surgeons in Ireland.

The following candidates having passed the necessary examination have been admitted Fellows of the College:—John Armstrong, B.Ch., &c., Roy. Univ., Ire.; S. C. Clarke, L.R.C.S.I., &c.; Raghunath Vithal Khedkar, L.R.C.S., &c., Edin.; G.W. Little, L.R.C.S.I., &c.; A. A. W. Merrick, L.R.C.S.I., &c.,; and F. J. Palmer, L.R.C.S.I., &c., Captain R.A.M.C.

Irish Medical Schools and Graduates' Association.

The thirtieth annual general meeting of the Association will be held at the Hotel Cecil, London, on Saturday, March 16th, 1907, at 6.30 p.m., when it is particularly requested members will make an effort to attend. On the same evening the members of the Association will dine together at the Hotel Cecil, at 7.15, the president, Sir John William Moore, in the chair. Lieut.-Col. Rt. Hon. Sir Albert Hime, K.C.M.G., Ex-Premier of Natal, will be the guest of the Association.

Indian Medical Service.

Lieutenants to be Captains: R. Kelsall, M.B.; J. H. Burgess, M.B., F.R.C.S.; C. H. Brodribb, M.B.; J. McC. A. Macmillan, M.B.; C. A. Gill; W. E. J. Tuohy; T. F. Owens; R. F. Steel, M.B.; G. F. I. Harkness; A. C. Ingram, M.B.; G. W. Maconachie, M.B.; E. W. C. Bradfield, M.B.; A. W. M. Harvey, M.B.; C. I. Brierley; J. B. D. Hunter, M.B., and E. T. Harris. This is in substitution for the notification regarding the promotion of these officers in the "London Gazette" of November 13th, 1906.

M. Daniel Osiris, according to the *Figaro*, has left by his will a sum of £240,000 to the Pasteur Institute. The Pasteur Institute is already one of the best endowed scientific institutions in the world, and this windfall will provide it with an annual income of from £30,000 to £40,000.

The Exeter meeting of the British Medical Association will open on July 29th by a reception of memers by the Mayor of the town, Mr. W. H. Reed.

WEEKLY SUMMARY OF MEDICAL LITERATURE, ENGLISH AND FOREIGN.

Specially compiled for THE MEDICAL PRESS AND CIRCULAR.

RECENT SURGICAL LITERATURE.

Trauma of the Abdomen.—In the *New York Medical Journal*, January 19th, 1907, A. E. Sellenings reports some cases of injury to the abdomen. He believes a study of the ætiology of these class of cases to be of great importance—the condition of the abdominal parieties, whether muscular or not; the hollow viscera, whether full or empty; the injury applied, whether it be slow moving or rapid; the amount of fat present. The recognition of the true lesions present after the trauma is very difficult. The resulting symptoms may be at once so meagre or so varied that no symptoms, or group of symptoms are of avail in establishing a diagnosis in most cases; shock, while often present, may be entirely absent. The author believes he is justified in drawing the following conclusions:—1. The diagnosis of traumatic lesions of the abdomen is most difficult. 2. The signs and symptoms are variable in their exhibition, and admit of no classification. 3. When there is an element of doubt in diagnosis, laparotomy is indicated. 4. History and nature of the injury may be the only indications for operation. 5. Early laparotomy will improve the percentage of recoveries. 6. Laparotomy, as a means of diagnosis, is without danger. 7. Tamponade is the best treatment for hæmorrhage in ruptures of the liver. G.

Fixation of the Bones in Excision of the Knee.—H. Groves describes a method (*Lancet*, February 23rd, 1907) which he has found very satisfactory in fixing the bones after excision of the knee. The method consists in cutting the bones with a mortised joint instead of leaving two smooth surfaces. The fixation is done by two metal rods, which are passed through the femur and tibia about three inches above and below the line of the excision. The rods project for a couple of inches on either side of the limb. Their free ends are then clamped together by two binding screws, which can be tightened until the joint is quite firm. These binding rods are removed under gas about two weeks after the operation. The author claims the following advantages for this operation:—1. That it fixes the bones together more firmly and more rigidly than any other method, because the fixation acts on dense bone of the shaft and not on the soft cancellous tissue. 2. That the bones are transfixed and held at points well away from the diseased area. 3. That the final fixation and tightening can be effected after the wound is sewn up and the limb placed on a splint. 4. That it saves the patient a great deal of pain in the dressings after the operation. 5. That it leaves no foreign bodies in the bones which may have to be removed by a subsequent operation. G.

Total Resection of the Thorax for Empyema.—C. Bayer believes that the chief dangers (*Zentralblatt für Chir.*, January 5th, 1907) in carrying out radical operations for long standing empyemata, which require extensive resection of the chest wall, are danger from hæmorrhage and from shock. The aim of his operation is to make his incision in such a way that there will be almost no hæmorrhage; that it divides only skin and connective tissue, going between the muscles in most cases, and cutting only unimportant muscles, while it still gives rapid and free access to all the ribs. The incision starts from a point about two inches behind the anterior axillary line, crosses this line close to the insertions of the serratus major, from the third to the tenth ribs. This incision causes almost no bleeding, and no muscles are cut, with the exception of a few fibres of the external oblique. The ribs, as many as are required, are then removed subperiosteally and the pleura opened with a thermo cautery. The operation can be easily and quickly performed, the drainage provided being in all cases excellent. G.

The Urinary Analysis of Operative Cases.—S. E. Tracy believes that surgeons (*New York Medical Journal*, January 19th, 1907) do not pay enough attention to the condition of their patients' kidneys, both before and after operation. He has carried out a research on this subject on a number of his own cases, and found that in 105 patients who had minor operations performed, twenty-seven per cent. had casts in the urine following the operation; of 123 patients in whom laparotomies were performed, in thirty-seven per cent. casts were found in the urine after the operation, while of 228 other cases operated upon nearly all of whom had ether anæsthesia, in thirty-three per cent. some change in the kidney occurred, as was evidenced by the presence of albumin, and epithelial, bloody, granular, or hyaline casts. Kelly has already drawn attention to the fact that chronic nephritis is frequently associated with malignant disease. The writer concludes his paper with the following remarks: That of the patients who come to hospital for operations, from fifteen to twenty per cent. suffer from some change in the kidneys, as is indicated from a careful study of the urine in every case. That the urine should be measured and examined for several consecutive days before a patient is given a general anæsthetic. That a chemical examination of the urine alone is not sufficient, and that in every uranalysis a careful microscopic examination should be made. That the urine should be measured and examined from every patient after a general anæsthetic has been administered, for should such a change take place in the urine the patient should be confined to bed, be kept very warm, and given saline, either by the rectum under the skin or by the mouth if the patient is not sick. With care such a condition will not last more than about six days, when the urine will once more become normal. Should the nephritis be neglected it may lead to permanent mischief in the kidneys. G.

Duodenal Ulcer and Its Treatment.—Mayo Robson (*British Medical Journal*, February 2nd, 1907) points out that operative experience shows that in a large proportion of cases duodenal and gastric ulcers coexist, and that the real proportion of duodenal to gastric ulcers is 1 to 2, or thereabouts. Gastric ulcer is commoner in women; duodenal ulcer is more frequently found in males. In the author's experience 86 per cent. in males to 14 per cent. in females. Most duodenal ulcers are within four or five inches of the pylorus. Dr. Ochsner has shown the presence of a sphincter just below the entrance of the bile and pancreatic ducts, and the duodenum above this has quite as much to do with digestion as has the stomach itself. There is apparently justification for classifying together ulceration of the stomach and duodenum. The symptoms often differ, however. Gastric ulcer is amenable to medical treatment in the earlier stages. It is questionable when duodenal ulcer has been recognised by definite symptoms, if it can ever be permanently cured by medical treatment alone. The clinical history of duodenal ulcer is more indefinite than in gastric ulcer, and symptoms may persist for a very long time in the former. Duodenal ulcer is commonest in the middle-aged. Pain is an important symptom. It comes on two to four hours after a meal, that is, when the stomach pours its acid contents into the duodenum. At this stage pain is sometimes relieved by food, because the acid is absorbed by the food in the stomach and the pyloric orifice closes for a time. The usual time for pain is at noon, about 5 p.m., and toward midnight. Pain tends to radiate towards the right loin and not towards the subscapular region as in gastric ulcer. Duodenal ulcer is usually characterised by periods of comparative good health between acute seizures. These periods may extend to weeks or months. In the acute stage there is rigidity of the right rectus, and tenderness usually just a little above and to the right of the umbilicus. Flatulency is more marked in duodenal than in gastric ulcer. There is dilitation of the stomach and hyperchlorhydria. It is exceptional to find any tumour. Acid eructations and heartburn are more frequent symptoms than vomiting. Appetite in many cases is good. Constipation is a very common symptom. Nutrition may not be seriously interfered with, but mental depression is common. A slight icteric tinge is almost constantly present in many cases. Also indican is usually found in the urine. Hæmorrhage and perforations are the most serious complications. Other serious complications are anæmia; cicatricial contractions leading to stenosis and secondary dilitation of the stomach; jaundice, pancreatic trouble, subphrenic and other abscess, disabling adhesions. Hæmorrhage is sometimes the first symptom to attract attention to duodenal ulcer. It is seldom revealed by hæmatemesis, as it usually passes downwards. Perforation is one of the most serious and frequent complications. Fortunately the gastric and duodenal contents at the time of perforation are only slightly septic, so that early operation should offer a good chance of success. Any other treatment than operation is useless. Repair of the rupture, simple drainage of the area of operation, and, if needful, drainage of the pelvis by the long tube inserted through an incision over the pubes, the drainage being assisted by the semi-recumbent posture, is all that should be done. Evisceration is unnecessary and dangerous. The author expresses a very decided opinion that posterior gastro-enterostomy is *the* treatment for duodenal ulcer. Subsequent to the operation the patient is always placed in bed well propped up, in fact, almost in a sitting position. Saline fluid per rectum in large quantities subsequent to the operation is of great service. As soon as the nauseating effects of the anæsthetic have passed off, one ounce of albumen water or other bland fluid is given every hour, and the following day two ounces every hour. The administration of food at frequent intervals is advisable for some time after operation, in order to absorb and neutralise the irritating acid of the gastric juice.

S.

The Surgical Treatment of Chronic Dysentery.—Captain Tucker, I.M.S. (*Indian Med. Gazette*, Feb., 1907) recommends appendicostomy in the chronic sloughing colitis of dysentery. He reports the following case. The patient, a man, æt. 30, had dysentery for four months. He had had another attack two years previously. He suffered from profound anæmia and marked wasting. In spite of medical treatment, patient got worse, passing four to seven large motions daily. The motions were bile-stained and offensive, and contained large pieces of sloughed-off mucous membrane. Operative treatment was undertaken. The appendix was exposed, and the cœcum sutured to the peritoneum of the anterior abdominal wall, three-quarters of an inch of appendix being left outside the wound. Four days later the tip of the exposed appendix was snipped off, and a No. 4 rubber catheter was introduced into the large intestine through the stump. Seventy-three ounces of a 1 in 400 solution of protargol were introduced. The following day the patient said he felt much better. Four fluid motions, each containing large sloughed-off pieces of mucous membrane, were passed. Sixty-three ounces of the same solution were injected. The injections were continued daily. After the fourth day the injections passed through the bowel without bringing away any more sloughs. On the ninth day the stool consisted simply of the irrigating fluid containing a large amount of undigested curds. The patient's general condition had greatly improved. During a slight attack of bowel irritability an astringent injection was used, and after some further delay in the stage of convalescence the stools became formed, of normal number, and gradually regained the pigmented condition which is characteristic of the normally functuring liver. The author considers this procedure much to be preferred to colostomy.
